As described above, there are four possible failure mechanisms that may be encountered as a result of the exposure of an adhesive joint to water. If we also consider the cohesive failure that may occur in a dry joint or a joint exposed to water for a relatively short time, there are five potential modes of failure. Of these five, four may look remarkably similar, and upon cursory examination, all will be described as an interfacial failure. This can be a gross oversimplification, and it is now informative to consider the characteristics of the failure modes that will be generated by each process in turn. The types of failure can be divided into cohesive failure within the adhesive (**Figure 3(a)**) or interfacial failure, when separation occurs exactly at the junction between substrate and adhesive (**Figure 3(b)**). Although conceptually easy, this definition is extremely difficult to confirm in practice as the layer of adhesive remaining on the substrate can range from many hundreds of micrometers (which can be established with the naked eye) to vanishingly thin layers of a few nanometers or less, which require surface analysis methods to detect and identify them. Thus, one of the greatest problems faced by those attempting to classify a failure mode can be the experimental techniques at their disposal; at some point, if only microscopy is used, a cohesive failure will appear, and be classified, as an interfacial failure!

If a joint is tested in a dry condition or if only exposed to water for a short time, the expectation is that the locus of failure will run through the glue-line thickness, a phenomenon that is readily observed by optical or electron microscopy and even, in some instances, by the naked eye. The diagnosis of such a failure is simple, but the edges of the joint should be examined for evidence of an interfacial failure generated by water diffusion along the interface. Even in instances of dry failure, it is possible that under some loading geometries, the locus of failure will pass so close to the metal–adhesive interface that the failure will appear interfacial to all forms of microscopy. This is the nub of any investigation into an adhesive joint failure – the identification of the failure path (or locus of failure to use the adhesion scientists term) at the molecular level. Thus, unless a failure

is demonstrably within the glue-line thickness, the emphasis is on the investigator to use techniques that are appropriate to characterize the exact locus of failure and also the thermodynamic or electrochemical cause of the failure under consideration. The most useful method for failure analysis in this type of investigation has been shown to be XPS, which is a surface chemical analysis technique with a characteristic sampling depth of  $\sim 5$  nm. In addition, XPS is able to provide chemical specificity, a quantitative analysis, overlayer thickness values and the identification of any characteristic ions from solution that are associated with the failure, and for this reason, it has been widely used in adhesion investigations over the last three decades.<sup>21–23</sup> The XPS characteristics of a cohesive failure close to the metal polymer interface are shown in **Figure 6**. This sample is a tin free steel substrate coated with an epoxy lacquer that has been hot molded to nylon, and then tested on a lap shear configuration. A macroscopic image (**Figure 6(a)**), shows that the failure appears to occur between metal substrate and epoxy or epoxy and nylon, depending on the position on the failure surface. Small spot XPS analyses (at  $400\mu\text{m}$ ) were taken from the region that appeared to be a metal interfacial failure surface and a mirror image position on the adhesive side. These spectra (**Figures 6(b) and 6(c)**) are extremely similar, and the characteristic of the epoxy coating itself is showing that the locus of failure is within this phase and not at the epoxy–steel interface, as one would assume from a visual inspection of the failure surfaces. Moving on to the situation wherein water is responsible for the (hydrodynamic) displacement of the adhesive from the metal substrate, an example can be seen in the work of Kinloch *et al.*<sup>24</sup> on the structural adhesive bonding of aluminum. After fatigue tests of a tapered double cantilever beam test piece, the joint is cracked open, and XPS analysis of the metal failure surface (**Figure 7(b)**), when compared with the unbonded surface (**Figure 7(a)**), indicates that an interfacial failure has occurred. However, the absence, in the spectrum, of any specific marker ion indicating electrochemical activity leads to the conclusion that this failure has been the result of the thermodynamic displacement, by water, of the adhesive from the metal substrate. This conclusion is entirely logical as the aluminum substrate will be covered with a passive oxide film and will only be susceptible to localized corrosion at points of metallurgical heterogeneity such as intermetallic precipitates (which will be cathodic to the surrounding matrix).

The observation that the electrochemical history of an electrode could be deduced from the spectrum

**Figure 6** Optical microscopy image of a failure between epoxy coated tin-free steel and a nylon coating (a). XPS survey spectra taken from the apparent interfacial failure between the steel substrate (b) and epoxy coating (c). The similarity of the spectra establish unambiguously that the failure is a cohesive failure within the epoxy lacquer.

of ions adsorbed on the surface was first made by Castle and Epler,<sup>15</sup> using XPS, and more recently, work from the authors laboratory has extended this approach to analysis using ToF-SIMS. The important observation, initially made more than 30 years ago, was that if a metal electrode is exposed to a cathodic potential in an aqueous electrolyte, it will, not unreasonably, adsorb cations from the electrolyte. On removal from the electrolyte and subsequent washing, these adsorbed ions are retained (often at submonolayer concentrations) on the electrode surface and can be detected and quantified by a surface chemical analysis technique such as XPS. Initial work envisaged that such an approach would be useful in identifying whether a corrosion feature, such a pit, was active or benign, but the widest application of this approach is probably in guiding the definition of failure mode of organic coating and adhesives. This can be illustrated from very early work on the delamination of an organic coating from cathodically

polarized ( $-1.5\text{ V}$  versus saturated calomel electrode in  $0.5\text{ M NaCl}$ ) steel.<sup>10</sup> The test was set up as shown in Figure 5 with a central defect in the coating so that the cathodic reduction reaction could readily occur at the exposed metal surface and lateral diffusion of hydroxide ions could occur unimpeded. In addition, water could diffuse through the thickness of the coating in regions well removed from the coating defect. The metal interfacial failure surfaces that are generated in these two regions are very different, as shown in Figures 8(a) and 8(b). The failure close to the defect is once again characterized by an interfacial failure, but the very intense sodium concentration ( $\sim 7\text{ at.}\%$ ) shows that there has been cathodic activity, the  $\text{Na}^+$  acting as a counter ion for the cathodically generated  $\text{OH}^-$ . Farther from this defect, the carbon peak in the spectrum is very intense and the Fe 2p peak (at a binding energy of  $\sim 710\text{ eV}$ ) is barely visible, being identified by an abrupt change in the background region of the spectrum. This change in background is

**Figure 7** XPS survey spectra from grit blasted/degreased aluminum surfaces (a) prior to bonding and (b) following failure after exposure to liquid water. Reproduced from Kinloch, A. J.; Korenberg, C. F.; Tan, K. T.; Watts, J. F. *J. Mater. Sci.* **2007**, *42*, 6353–6370.

itself very informative, in that it indicates to the electron spectroscopist that most of the iron signal is being attenuated by a thin overlayer of, in this case, carbon (polymeric coating). Thus, this spectrum indicates that the failure is cohesive within the polymer but with a very thin (<10 nm) overlayer, indicating the locus of failure is ~10 nm from the metal oxide–polymer interface.

Although failure of adhesion as a result of cathodically generated alkali is one of the most usual failure mechanisms when corrosion is involved, there are very few documented examples of the advancing disbondment front acting as an anodic crevice. The most cited system and example of great importance to the food packaging industry is the anodic undercutting of the tin coating on tinplate<sup>18</sup> in times gone by but less so nowadays. An example of the manner in which the polymer–metal interface may develop as

anodic crevice is afforded by the work of Castle *et al.*<sup>19</sup> who investigated the failure of an acrylic coating on aluminum brass on exposure to hot saline solution. The XPS survey spectra of Figure 9 are from the interfacial failure metal surfaces of the acrylic–aluminum brass systems when subjected to a mechanical test before exposure (Figure 9(a)) and the failure following saline exposure (Figure 9(b)). Both failures are cohesive, as indicated by the intense C 1s peak at a binding energy of ~285 eV, and the intense Cl 2p peak for the exposure surface (Figure 9(b)) is in marked contrast to the failure surfaces of Figure 8(a) and indicates that the system is behaving as an anodic crevice. The localization of anodic activity within the crevice was reported to be enhanced by the application of increased thickness of organic coating, which represents a situation similar to that in adhesive bonds.

**Figure 8** Failure of a polybutadiene coating on steel exposed to the cathodic disbondment test of [Figure 5](#). XPS survey spectra from (a) immediately adjacent to the defect, resulting from the cathodic generation and lateral diffusion of hydroxide ions and (b) the wet adhesion failure region well removed from the defect arising from the downward diffusion of water molecules through the thickness of the coating. In this section, the various mechanisms that may be observed in adhesive joints exposed to aqueous environments have been reviewed. When inspecting a failure surface, the first step in establishing the process responsible for failure is the assessment of the exact locus of failure. If failure is clearly within the glue-line thickness, as established by visual inspection or optical or electron microscopy, then it is reasonable to assume that failure is a result of exceeding the load-bearing capacity of the adhesive, and corrosion does not play a significant role in the

**Figure 9** The failure of an acrylic coating on brass. XPS survey spectra of the interfacial metal surface following (a) dry test and (b) test in hot saline solution. Reproduced from Castle, J. E.; Luklinska, Z. B.; Parvizi, M. S. *J. Mater. Sci.* **1984**, *19*, 3217–3223.

failure process. If the failure path is very close to the substrate–adhesive interface, it is very likely that degradation based on exposure to water or corrosion reactions is responsible for failure, and without resorting to surface analysis techniques, such as XPS, it is probable that the locus of failure will be described as interfacial, even if examined at high resolution in an SEM. The reason for this is that failure is often extremely close (within 10 nm) to the interface, and thus, to fully understand failure, a surface chemical analysis is needed. A true interfacial failure can be easily recognized (although there will be a small amount of adventitious carbon – 20–35 at.% in a quantitative surface analysis), and this may be a result of hydrodynamic separation on exposure to water or cathodic delamination, which is recognized by the adsorption of cations, such as sodium, from the

test solution. If there is a small residual layer of adhesive on the substrate, it may be a result of water- or alkali-induced degradation of the polymer phase; once again, the presence of cations will indicate a significant involvement of the cathodic reduction process. The presence of anions, such as chloride, to excess, is unusual and is indicative of failure being the result of a developing anodic crevice, and seems to be associated with a cohesive failure.

Having reviewed the corrosion processes that may be responsible for failure of an adhesive joint and the manner in which the forensic analysis of failed surfaces can help identify the failure mechanism, and the role of corrosion in the failure process, it is helpful to consider the failure characteristics of various adhesively bonded substrate materials.

### 3.36.4 Adhesively Bonded Substrate Materials

In this section, the role of corrosion in adhesive bond failure will be considered with a series of case histories involving common metallic substrates for adhesive bonding. It is interesting to note that some authors set out to establish performance data, which can be used for adhesive bond design purposes, and the unraveling of the failure mechanism, takes on a secondary role, while others set out with the main purpose of establishing failure mechanism and use durability data on a merely comparative basis. It is important to note that there are two clear philosophies that are in use regarding the durability testing of adhesive joints; the first, easiest, and probably least realistic is to expose the joint to the aggressive environment with no load applied: at the point of test, the joint is removed from the test solution, dried, and

tested, to obtain performance data. The alternative approach is to load (either monotonically or in cyclic mode) within the test environment, and once failure has occurred, remove specimens for microscopy and/or analysis. Both methods have their own particular merits; the first practice avoids the possibility of post-failure contamination (or back deposition) from the test solution, while the second is clearly much more realistic and generates data that can be included in the appropriate design codes. Examples of both types of testing will be considered in this section.

#### 3.36.4.1 Low Carbon Steel Substrates

As one might imagine, the rapid corrosion that is experienced by adhesively bonded low carbon steel, if the joint is not protected by additional measures, leads to the domination of cathodic delamination as a failure process, and significant problems in the post failure analysis of failed joints as all surfaces that have been exposed during failure will inevitably become anodic sites. There are two potential measures for alleviating these difficulties; the cathodic polarization of the entire joint and the exposure of a joint in water with a low concentration of dissolved oxygen. Both approaches have been successfully employed, and examples are described below.

The bonding of neoprene to mild steel is of particular importance in the maritime industry, and there is a fairly extensive body of literature dealing with the failure modes of this system when the steel substrate is protected by either impressed current or sacrificial anode cathodic protection. The mechanistic aspects of the failure of this system was investigated by Boerio *et al.*<sup>25,26</sup> who employed a strip blister specimen, illustrated in Figure 10, polarized at a

**Figure 10** Schematic diagram of the strip specimen used for the study of the cathodic delamination of neoprene rubber from steel. Reproduced from Boerio, F. J.; Hudak, S. J.; Miller, M. A.; Hong, S. G. *J. Adhes.* **1987**, 99–114.

potential of  $-1.5\text{ V}$  versus the saturated calomel electrode. They were able to show, by XPS and FT-IRS analysis of the failure surfaces, that degradation occurred as a result of the degradation of the phenolic primer and dehydrohalogenation of the rubber in both the primer and the adhesive.<sup>25</sup> Such dehydrochlorination resulted in the formation of inorganic solutes soluble in the alkaline solution used as a test medium. These authors also showed a critical dependence on surface roughness, indicating the importance of mechanical effects in the performance of adhesive joints, presumably as a result of the increased extent of interfacial contact achieved with the rougher substrate. In subsequent work, Boerio and Hong<sup>26</sup> used FTIR to refine the chemistry of the failure mechanism, and showed that methylene groups linking phenyl species in the primer were rapidly oxidized in alkaline solution to form benzophenone linkages, which could oxidize further to carboxylic acids and quinines.  $\text{ZnCl}_2$  was observed to form a soluble reaction product at the bondline, as a result of the reaction between chlorine from the chlorinated rubber and  $\text{ZnO}$  filler in the primer. It is concluded, on the basis of these studies, that both the oxidation of phenolic resins in the primer and osmotic effects related to  $\text{ZnCl}_2$  have important roles to play in the failure mechanism of rubber to steel adhesive joints. Complemented by the studies of Hamade and Dillard, in a series of papers spanning almost 20 years, have concentrated on relating the experimental observables (strength and extent of disbondment) to experimental parameters, such as time, temperature, and cathodic potential. The study of these authors is informative as it shows how a simple, diffusion-based model can be developed to provide a semiempirical model that is able to accurately predict the disbondment rates upon exposure to cathodic environments. These authors also differentiate between a separated zone (the picture-frame failure appearance) and a weakened zone ahead of the true delamination zone. Although mechanistic aspects of this are not fully explored, one assumes that the separated zone is the region of cathodic delamination resulting from alkaline attack of the interfacial bonding, while the weakened zone results from aqueous plasticization of the adhesive. The latter zone may show recovery of strength on removal from the aqueous environment as described by Watts *et al.* in their work on epoxy and other systems.<sup>27</sup> Hamade *et al.* in their extensive studies have produced data on the rate of disbondment in both the failed and weakened zone, and also strain energy release

rate,  $G$ , as a function of time. This led to the development of a semiempirical model for the cathodic weakening of adhesive joints,<sup>28,29</sup> in which failure kinetics were related to the harshness of the environment (as exemplified by extent of cathodic activity and temperature of test) and the strain energy release rate. This can be represented very conveniently in the diagram of **Figure 11**, which illustrates the generic behavior of delamination rate ( $\log dZ_2/dt$ ) versus strain energy release rate for weakening (region I), delamination (region II) as well as region III, where environmental and corrosion process play no discernible role in the failure process. These authors also provide guidance on the extent of delamination that will occur for a given set of exposure conditions in the form of nomographic scales or nomograms. In this manner, the extent, for a particular bond, in a particular aqueous environment, can be estimated as a function of cathodic potential and temperature. Two such nomograms are reproduced in **Figure 12** for a mild steel adhesively bonded system of a chlorinated rubber adhesive and a phenolic resin/chlorinated rubber primer. **Figure 12(a)** represents the calculated delamination values ( $Z_2$ ) for the above system in artificial seawater, while **Figure 12(b)** represents complementary data in a 1M NaOH environment. The arrows on the nomograms indicate example applications for the time for 12 mm of delamination to occur in the strip blister test of **Figure 10** at a potential of  $-1100\text{ mV}$  and at a temperature of 298 K. In the case of artificial seawater, a time of 180 days is predicted, while in 1M NaOH, a much reduced time of  $\sim 30$  days is indicated. Although very specifically related to a certain system, such nomographs are clearly of much practical use, allowing changes in environment and pretreatment to be predicted.

An alternative way in which gross corrosion of a mild steel substrate can be alleviated in order to examine the interfacial chemistry associated with failure is to expose the joints in water containing a low concentration of dissolved water. In studies of this type, Davis and Watts<sup>30</sup> assembled adhesively bonded mild steel coupons in a lap shear configuration and then immersed them in pure water in sealed glass jars, removing specimens periodically for mechanical testing and surface analysis of the interfacial failure surfaces. After 1200 h of testing, a characteristic picture-frame failure surface was observed, while after 7500 h, the picture was greatly reduced in size, and visual and spectroscopic differences were observed at the surrounding metal surface. In the early stages of exposure, adhesive-substrate separation is driven by cathodic delamination, but on longer exposure times,

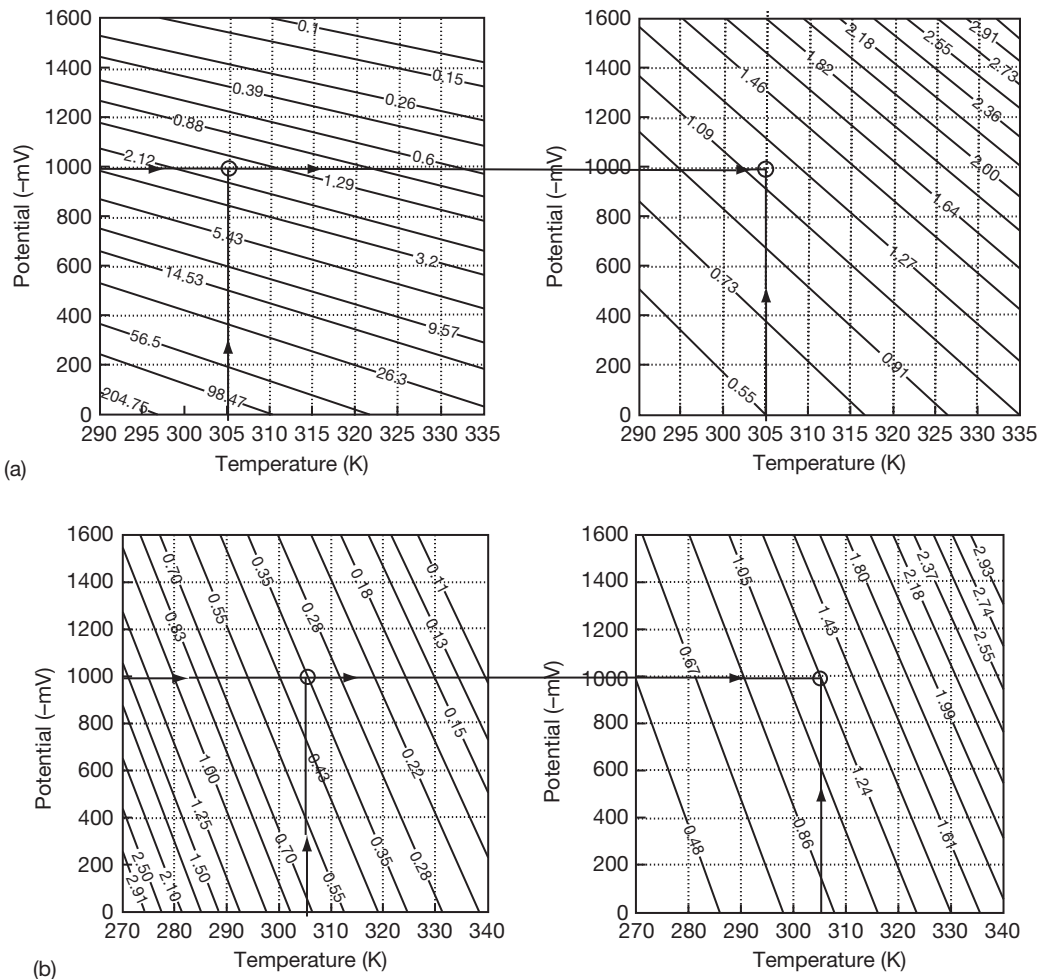

**Figure 11** A plot illustrating the generic behavior of log delamination rate ( $\log dZ_2/dt$ ) versus  $\log G$ . The diagram shows the regimes of diffusion control, leading to weakening (region I), the mixed diffusion/reaction control region (region II) and the environment independent region (region III). Reproduced from Hamade, R. F.; Seif, C. Y.; Merhij, F.; Dillard, D. A. *J. Adhes. Sci. Technol* **2008**, 22, 775.

the crevice opens at the mouth as a result of oxide thickening, which appears as a dull rather than bright outer region. XPS analysis confirmed oxide dissolution at the crack tip with oxide growth subsequently occurring, as indicated in [Figure 13](#). As the experiments were undertaken in pure water, the deposition of marker cations was at a very low concentration (below the detection limit of XPS); however, ToF-SIMS, with its better detection limit, allowed such marker ions to be profiled across the failure crevice. This example illustrates the concept of a so-called zero volume debond (sometimes referred to as a kissing bond in the aerospace industry) in which the adhesive and failure surfaces are in contact but have no load carry ability as a result of the adhesion between the two, having been compromised.

### 3.36.4.2 Aluminum Substrates

As a result of its importance in the aerospace industry, the adhesive bonding of aluminum has been studied very widely over the last three decades, and there is a large body of literature relating to the

mechanical performance and durability of these systems. Generalized corrosion of aluminum is unusual, and it has very rarely been identified as a primary cause of failure in adhesively bonded systems, although localized corrosion in the form of pitting may sometimes be seen on test pieces immersed in water. The more usual forms of failure are associated with adhesive degradation at short exposure times, and interfacial separation of adhesive and oxidized aluminum substrate is as a result of thermodynamic displacement of adhesive by water. Using simple T-peel joints, exposed to water prior to testing, Watts *et al.*<sup>27</sup> were able to show failure associated with adhesive degradation at the edge of the joint. [Figure 14](#) shows the physical appearance of the failure surface of adhesively bonded chromic acid anodized aluminum following 10 weeks exposure at 50°C in deionized water. The characteristic picture-frame type of failure morphology is seen running along the length of the joint, and visual assessment would identify the edge effect as being an interfacial failure. Small area XPS analyses were recorded from the interfacial failure surfaces at the edge of the joint and the centre of the

**Figure 12** Nomographs for estimating bond weakening distances in (a) artificial seawater and (b) 1M NaOH. joint width. As expected, the general cohesive failure zone yields a spectrum characteristic of the bulk adhesive with no unexpected elements present, but the spectrum from the edge region, **Figure 15(a)**, is of an oxidized aluminum substrate attenuated with  $\sim 5$  nm of adhesive. This clearly indicates that failure is associated not with environmental attack of the adhesive–substrate interface but with the aqueous degradation of the adhesive itself. Work in this paper also shows that such degradation is physical rather than chemical in nature and that a drying schedule at elevated temperature is able to reverse the damage, the locus of failure moving into the bulk of the adhesive, as observed in the central part of the joint of **Figure 15(b)**.

As part of a wide-ranging fracture mechanics study, Kinloch *et al.*<sup>24</sup> have studied the durability of

adhesively bonded aluminum joints, steel joints, and aluminum–steel couples bonded in a similar manner. In the case of the aluminum and steel joints, the failure mechanisms were as expected; in the case of bonded 7075 aluminum, there is little corrosion observed, and failure is attributed to the thermodynamic displacement of the adhesive from the substrate as predicted by eqn [2]; when the substrates are both medium carbon (0.6%), steel failure follows the predicted path of cathodic delamination, both failure mechanisms being confirmed by an extensive XPS and ToF-SIMS study. In the case of dissimilar substrates (aluminum and steel beams), the situation is rather complex, and it is worthwhile considering this situation in some detail as an exemplar of how corrosion processes may have an unexpected role to

**Figure 13** Schematic illustration of the failure processes that occur within the extending crevice at the edge of an adhesive joint exposed to an aqueous solution with a low partial pressure of oxygen. The crevice mouth acts as the anode and subsequently opens as a result of oxide growth and other processes, while the crevice tip forms the cathodes and leads to a zero-volume debond within which mass transport of the reactive and other species is restricted. Reproduced from Davis, S. J.; Watts, J. F. *J. Mater. Chem.* **1996**, 6, 479–494.

**Figure 14** The schematic appearance of the failure surface of a T-peel assembly of adhesively bonded aluminum exposed for water at 50°C prior to testing. Reproduced from Watts, J. F.; Blunden, R. A.; Hall, T. J. *Surf. Interf. Anal.* **1990**, 16, 227–235.

play in the failure of an adhesively bonded structure, and the manner in which it is necessary to consider the environment surrounding the joint as well as the specific environs of the bondline itself. In the case described by Kinloch *et al.*, the joints were assembled in a tapered cantilever beam geometry (to ensure constant compliance as crack propagation occurs) and tested under fatigue loading in pure water. Failure always occurred adjacent to the adhesive–steel interface, and not at the aluminum–adhesive interface. At first sight, the occurrence of the failure at the

**Figure 15** Small area XPS (250 μm) taken from the edge (a) and the central (b) regions of the failure illustrated in Figure 14.

steel–adhesive interface would seem to be the simple case of galvanic corrosion, as an aluminum alloy will be at the more active end of the galvanic series than steel. For such galvanic coupling to occur, there needs to be electrical contact between the aluminum–alloy

and steel substrates. This was not the case, and experiments were performed to ensure that there was no electrical coupling of the two substrates. There was also extensive corrosion on the steel beam, which would not be present had the beam been the cathodic part, in its entirety, of a galvanic cell. Now, the reason for the inferior durability of the dissimilar joints lies in the diffusion of oxygen molecules into a developing crevice and the concomitant outward diffusion of the cathodic reaction product ( $\text{OH}^-$ ). It is helpful at this point to consider the situation in terms of the oxygen supply that exists for the steel–steel joint. Along the sides of both beams, the anodic reaction will take place, and soluble  $\text{Fe(II)}$  ions will pass into the solution, leading to a local increase in density. Thus, this solution of water and  $\text{Fe(II)}$  ions will sink to the bottom of the testing tank, and the solution in the environs of the adhesive layer will be refreshed with aerated water. This situation ensures that there is a ready supply of reactants for the cathodic reaction, which develops a crevice normal to the direction of crack propagation (i.e., the length of the test piece). As the diffusion of hydroxyl ions is known to be rapid in aqueous solution, it is more likely that the aggregation of these species at the crack tip is modest; in other words, the diffusion coefficient of water molecules into the crevice is much the same as that of hydroxide ions diffusing outwards. Thus, the rate-controlling step may be taken to be the rate of arrival of the water molecules, which must feed the two developing cathodic crevices. This situation is illustrated schematically in **Figure 16**. In the case of an aluminum–alloy–steel

joint, the two metal interfaces will not behave in the same manner; the steel adhesive interface will develop a cathodic crevice as described above, but as the aluminum–alloy has a passivated film present, the extent of cathodic reactions at this surface will be confined to regions surrounding localized corrosion, such as pitting on the failure surface of the beam. Thus, any corrosion on the aluminum–alloy beam will be a post-failure event. This means that the majority of the oxygen molecules dissolved in the aqueous bath adjacent to the adhesive layer are available for consumption by the cathodic half reaction at the steel–adhesive interface. Assuming the outward diffusion of hydroxide ions remain the same, the situation that now exists is that the inward diffusion of oxygen molecules exceeds the outward diffusion of hydroxide ions. This will lead to an aggregation of hydroxide ions at the crevice tip and an increase in pH in this region. This will have an increased damaging effect on the level of adhesion between adhesive and steel substrate and the associated reduction in performance. To summarize, the increased concentration of oxygen molecules available in solution to feed the crevice developing normal to the beam side at the steel–adhesive interface weakens the joint and leads to more rapid advancement of the crack tip. As the crevice develops, the crevice mouth becomes anodic and the corrosion product is back deposited, reducing the inward diffusion of water and oxygen molecules, but by this time, the damage is already done and the mechanical perturbation of the reduced area at the advancing crack tip has brought about failure. The development of the cathodic crevice

**Figure 16** Schematic illustration of the supply of oxygen to the crevices developing at the adhesive–substrate interface of an adhesive joint. As freshly aerated water arrives, it must supply oxygen to both crevices in the case of a steel–steel joint, but only the steel–adhesive interface in the case of an aluminum–steel joint. Reproduced from Kinloch, A. J.; Korenberg, C. F.; Tan, K. T.; Watts, J. F. *J. Mater. Sci.* **2007**, *42*, 6353–6370.

happens along the beam simultaneously; thus the effect is most serious in the mid-regions where the crevice has developed significantly but not been blocked by corrosion product. The situation is summarized schematically in **Figure 17**.

### 3.36.4.3 Zinc Substrates

The need to bond zinc structures is, of course, very specialized and outside the scope of the review; however, the bonding of zinc coated steel (whether hot dipped or electrogalvanized (HDGS or EGS)) is becoming increasingly important as a production process, particularly in the automobile industry. In essence, the failure is brought about by the gross corrosion of the substrate, a situation that is improved by the chemical pretreatment of the substrate, for example, by the application of a zinc phosphate process. Dickie *et al.* showed quite convincingly that the failure

of adhesively bonded EGS in an aqueous environment is a result of an electrochemically driven process,<sup>31</sup> with the XPS survey spectra of both the metal and adhesive interfacial failure surfaces being dominated by zinc oxide. These observations indicate that failure is associated with gross corrosion of the zinc when the surface is not stabilized by the application of an appropriate treatment, such as a conversion coating. Work by Fitzpatrick *et al.*<sup>20,32</sup> points the way to a better understanding of the manner in which such a conversion coating improves bond durability. Studies by small area XPS indicate that failure initiation is associated, at least in part, by the dissolution of the phosphate crystal by cathodically-generated alkali in regions of some 50–100  $\mu\text{m}$  in size within 1 mm of the edge of the adhesive bond. ToF-SIMS successfully identifies electrochemical activity, although not gross phosphate dissolution, within the central region of the joint, and it is clear that this precedes the

**Figure 17** Schematic representation of the factors influencing supply of oxygen in the developing crevices. (a) In the early stages of failure, oxygen is supplied at the advancing crevice tip as the crack proceeds along the length of the beam and also normal to the direction of crack growth to establish a small but significant developing crevice at the edge of the specimen. (b) The edge crevice may become blocked with corrosion products in this manner in the later stages of joint failure and thus have a disproportionate effect on the failure kinetics. Reproduced from Kinloch, A. J.; Korenberg, C. F.; Tan, K. T.; Watts, J. F. *J. Mater. Sci.* **2007**, *42*, 6353–6370.

phosphate degradation process identified at the bond edge. This points the way to a more purposeful design and selection of conversion coatings for the pretreatment of zinc-coated steel for adhesive bonding, the use of those that have a better resistance to alkaline dissolution than the traditional zinc phosphate product.

### **3.36.5 The Improvement of Bond Durability**

The solution to the need to improve the resistance of adhesive joints to the ravages of corrosion-related phenomena, leading to premature failure, is well-catalogued and can be readily appreciated by consideration of the examples above. There are two potential routes by which durability can be improved; one is the exclusion or immobilization of water by the adhesive so that the kinetics of diffusion toward the reaction zone are reduced to a manageable or acceptable level. The other is to modify the interface in some manner so that the forces responsible for adhesion become less susceptible to cathodically generated alkali or the interfacial path length between substrate and adhesive, which is increased to such an extent that the delamination process at the interface translates to a lateral or planar value that will no longer compromise the joint performance.

Exclusion of water is most commonly achieved by the simple expedient of the application of a bead of silicone, polysulfide or similar sealant along the external surface of the adhesive. Similar in use to a typical domestic product for bathroom use, such a sealant not only seals the joint against the ingress of water, but being hydrophobic, it also physically repels water from the vicinity of the joint. A similar approach is to use a hydrophobic binder for the adhesive, which will repel water from the adhesive, although not necessarily from the interface region. An alternative possibility, not widely explored, is to add extenders to the pigment that will either absorb and immobilize water or increase the path length for water to reach the interface.

The modification of the interface to improve performance would seem to be a much more elegant approach to take, and clear improvements in performance can be achieved by the use of organo-functional silanes as either primers<sup>24,28</sup> or components of the adhesives formulation, and most commercial structural adhesives have these additives included by the manufacturer. The benefit derives from the formation of a bond more resistant to both hydrodynamic displacement

and cathodic delamination; that is a covalent bond as opposed to van der Waals bonding.<sup>33</sup> The increase of the interfacial path length is achieved by simple expedients, such as grit blasting, but in the case of aluminum, this is never adequate, and the complex microtopography achieved by acid anodizing processes is always required.<sup>34</sup> The porous deposit produced by these processes is filled by the adhesive on joint manufacture forming an interlocking region sometimes referred to as a microcomposite interphase zone.

The empirical test approach for a particular set of variables (substrates, adhesive type, loading conditions and environment) is an important way of extending our understanding of failure mechanisms and at the same time providing an indication of the manner in which improved performance can be obtained. This does not necessarily help the design engineer and certainly provides no predictive capability outside the narrow spectrum of conditions that have been examined. The solution to this, as outlined by many authors in recent years, is to develop predictive models that take into account the important variables that are experienced by adhesive joints. There are two basic approaches here that can be described, by analogy with nanotechnology production methods, as top-down or bottom-up. Models based on empirical results, of the required level of sophistication, can be extended to accommodate different adhesive bonding situations, and elegant examples of this approach is provided by the work of Kinloch<sup>24</sup> and Hamade.<sup>35</sup> The alternative approach is to consider a particular joint geometry, load and environment, and the development of closed form adhesive joint stress analyses as described by Crocombe.<sup>36</sup> The particular challenge with this method has been the incorporation of environmental degradation into such closed form solutions, and recent work shows that this can be achieved in a relatively straightforward manner.<sup>37</sup>

### **3.36.6 Conclusions**

There is a very large body of literature that documents the deleterious effect of water on adhesively bonded metal structures, and the prime causes of joint failure are well understood. Corrosion of the substrate, leading to cathodic delamination of the adhesive from the metal is particularly important in the failure of steel joints, while for aluminum, with its passive native oxide layer, thermodynamic displacement of the adhesive from the substrate by the water is the most

commonly encountered failure mode. If the interface is modified chemically (e.g., using an organosilane) or physically to increase surface topography and then the interfacial path length, environmental degradation of the adhesive itself may occur. In order to improve a joint performance, it is necessary to first define the failure mode, and the surface analysis methods of XPS and ToF-SIMS have important roles to play here, not only in the exact definition of the locus of failure, measurement of the thickness of vanishingly thin residual adhesive layers, and relating their composition to the adhesive formulation, but also in the identification of tracer anions and cations, which can indicate whether the region of the substrate that the adhesive has separated from has experienced anodic or cathodic condition as an electrochemical cell has been set up.

There is still much active research to establish new pretreatments that will improve the durability of joints and provide improved corrosion resistance of the substrate. The driving force over the last decade has been to remove hexavalent chromium from pretreatment processes, and the stage is almost upon us where this reagent can be removed totally from the pretreatment stage of the bonding process, even in the aerospace industry, with no adverse effect on performance.

### Glossary

**Millscale** An oxide that forms on steel during high temperature processing (e.g., hot rolling) and must be effectively removed prior to the application of any subsequent surface protection.

**Surfactant** A substance that lowers the surface tension of a liquid, allowing easier spreading across the surface of a material.

**Workpiece** The item, component, or material that is undergoing surface pretreatment.

### Abbreviations

**BS** British Standard

**EDTA** Ethylene diamine tetra-acetic acid

**EN** European Norm  
**ISO** International Standards Organisation  
**TLV** Threshold limit values  
**VOC** Volatile organic compounds

#### **4.01.1 Introduction**

The attainment of a clean surface prior to the application of any subsequent treatment or coating is essential, whether this subsequent operation is electroplating, anodizing, chemical treatment, or organic coating. The standard of cleanliness which must be achieved has been stated to be “that which will allow the subsequent process to be carried out satisfactorily”; however, this is an almost meaningless statement. Often it is industry experience that provides a guide to the standard of surface preparation required. As an example, the degree of cleanliness required to satisfactorily zinc plate from an acid solution is somewhat higher than that required prior to zinc plate from a high-cyanide alkali zinc solution. However, this should never be taken as a license to skimp on surface preparation and in another example the arguments over the degree of pretreatment required for ‘surface-tolerant’ paint coatings abound and will probably continue. It should be remembered that it is to a large extent true that problems of early failure in metal finishing are traceable to incorrect or insufficient surface preparation.

#### **4.01.2 Chemical Cleaning**

Chemical contamination consists of oils, greases, preservatives, or old paint coatings which must be removed prior to further finishing. Paint coatings can be removed by chemical paint strippers (e.g., solvent or alkali based); however, these methods will not be discussed further here. Sources of most organic contamination are, for example, cutting and machining fluids, preservatives, oils, and greases from, for example, rolling operations, press lubricants, and mechanical or manual handling operations. Various means of removal have been proposed: mechanical action; solvency; detergency; and chemical reaction. In all cleaning operations one or more of these mechanisms will contribute more or less to the overall cleaning procedure, dependent upon the cleaning method and solution employed.

With chemical cleaning, performance will be enhanced by the use of mechanical action, such as brushing, air agitation, spraying, electrolysis or ultrasonic agitation. Solvency is where the materials to be

removed dissolve in the cleaning medium, for example mineral oil in chlorinated solvents. Detergency is the ‘lifting’ action attributed to some alkalis and to special surface-active agents commonly referred to as surfactants. Chemical reaction is characterized by, for example, the saponification of some oils in strong alkali, or the reaction of rust with acid solutions. The main types of cleaners used for the removal of organic contaminants are solvent cleaners, neutral cleaners, acid cleaners, and alkali cleaners.

##### **4.01.2.1 Solvent Cleaning**

The traditional use of flammable hydrocarbon solvents (e.g., white spirit or paraffin) used either by immersion or by manual application is not to be recommended as an effective or particularly safe method of degreasing. When used by immersion, the holding tank can become heavily contaminated and the contaminants will remain on the work after the solvent has evaporated. The use of solvent-soaked rags, although a time-honored procedure, is now being frowned upon on the grounds of operator safety; aqueous based prewipes are available.

###### **4.01.2.1.1 Vapor degreasing**

The use of hot/boiling solvents, with either immersion of the articles to be cleaned in the bulk solvent or in the overlying vapor using specially designed installations, is an effective use of solvents for cleaning purposes. The solvent, which traditionally was of a halogenated hydrocarbon type, is held in a sump at the base, which is heated by any suitable means and under thermostatic control. Above this may be a wire mesh on which the workpieces are rested. The solvent is condensed near the top of the chamber by cooling coils; thus, between the mesh and the coils is created a region where the solvent is in vapor form. When cold items are introduced, the vapor condenses upon them and liquid solvent flows off, thereby removing contamination. To a large extent, only clean solvent is vaporized, thus ensuring that only fresh solvent is used to clean the workpiece until the sump becomes overcontaminated, when the solvent must be cleaned or replaced. Care should be exercised with some metals, notably aluminum, that solvent with free chloride is not used, as this could lead to pitting of the metal surface.

Currently, the use of chlorinated solvents is increasingly deprecated in view of the extent of release of volatile organic compounds (VOC). Therefore, the advice of the manufacturers of the installation and the suppliers of the solvent should always be heeded in the operation of these installations to ensure

their trouble-free running. Effective fume control must be available above the installation and the work must be removed slowly enough to ensure that all the solvent has evaporated from the work before it leaves the extracted area. Also, as per governing legislative rules, exposure limits for solvents are increasingly being reduced and current advice must be sought.

#### **4.01.2.1.2 Emulsifiable cleaners (water rinsable cold solvent cleaning)**

Emulsifiable cleaners (sometimes incorrectly referred to as emulsion cleaners) are blends of organic solvent (often hydrocarbons) with surface active agents and dispersed in an aqueous medium. The work is immersed in the unheated solution for a sufficient time for the cleaner to penetrate the surface thoroughly. The articles are then removed and water rinsed. Additives in the cleaner allow the solvent to emulsify in the water thus removing the contamination. Spray rinsing or agitation in an immersion rinse will aid removal of the residues. This form of cleaning creates disposal problems as the rinse water cannot be merely disposed of into sewerage systems. Thus, the effluent will require storage and the emulsion is broken up before discharge of the water layer and approved disposal of the organic material. As with all solvent-based materials, the need to observe threshold limit values (TLV) for personal exposure and the need for the work to be carried out only under effective fume extraction must be taken into account when considering this type of cleaning product.

The cleanliness of the surface produced by emulsifiable cleaners is not of the highest standard, and additional cleaning may well be necessary before further finishing operations. However, in the use of this method prior to some chemical conversion coating processes (e.g., immersion in phosphate baths), the crystal growth can be quite refined because of the absence of the passivation effect often encountered with some heavy-duty alkali cleaners. Needless to say, manufacturers' recommendations should be followed at all times and the suitability of any particular cleaning/pretreatment combination should be confirmed. Another benefit gained from the use of emulsifiable cleaners is that the surface produced is usually hydrophobic and therefore, to an extent, resistant to tarnishing and corrosion in storage.

#### **4.01.2.1.3 Emulsion cleaners**

These are materials, containing blends of organic solvents and surfactants, which are added to water to form an emulsion. Typical concentrations are in the range 0.5–5%. Such emulsions are normally used

by spray, as either a preclean in a multistage pretreatment line, or as the cleaner in an industrial washing machine. Such washing machines are often used to clean parts which are contaminated with cutting oils and which require inspection before storage. Like the emulsifiable cleaners, the emulsion cleaners, after rinsing, often leave a hydrophobic surface which is resistant to short-term corrosion. Emulsion cleaners can be used hot or cold. Heat generally improves the cleaning action but, in most cases, leads to an objectionable increase in the smell associated with solvent products.

#### **4.01.2.2 Neutral Cleaners**

These are rapidly replacing emulsion and alkali products for use in industrial washing machines and are generally used at pH 7.5–9, which is considerably lower than that of the corresponding alkali products. Neutral cleaners are on the basis of chemical soaps, with additions of surfactant (to improve cleaning, wetting, penetration, and defoaming), corrosion inhibitors (which may be nitrite or organic), and a bactericide.

Neutral cleaners provide the benefits of generally lower operating temperatures, reduced odor, easier effluent treatment, and improved health and safety considerations over the alkali or emulsion products. Because of the inhibited nature of the surface produced, such products are used for inter stage cleaning and prior to assembly. The surface is generally not suitable for immediate painting.

#### **4.01.2.3 Acidic Cleaners**

The vast majority of acid-based cleaning products are designed for the removal of scale, rust, and other oxide films. These products may also contain solvents and surfactants to degrease and derust simultaneously. There are, however, certain acid-based materials which can primarily be construed as cleaners. One such type of material is used in the cleaning of aluminum cans prior to treating and lacquering. Such cleaners are normally on the basis of sulfuric or phosphoric acid, with, generally, additions of hydrofluoric acid and surfactants. These materials are sprayed on to preformed cans to remove the lubricant used during the can-forming operation. The fluoride is present to enhance the removal of fine metal swarf as well as to remove the oxide film.

Fluoride-free acid cleaners are used for general pretreatment cleaning of aluminum as an alternative to strong alkali materials. Although more expensive in terms of initial make-up and plant requirements the rate of material loss through cleaning and etching is reduced. Furthermore, the need for an acid de-smut (required after alkali cleaning) can be eliminated.

As the surface smoothing and leveling effects are somewhat limited, the use of acid cleaners prior to anodizing or electropainting, where surface defects can be enhanced, is not common. Care must be taken here not to confuse acid cleaners with high-strength, phosphoric acid-based chemical polishes and chemical brighteners, which are used to obtain specific types of attractive surface finish. Also in the category of acid cleaners could be considered the lightweight alkali-metal phosphating cleaner-coater solutions; a fuller discussion of such materials is best left to specialist publications on metal pretreatment chemicals.

#### 4.01.2.4 Alkaline Cleaners

Alkali cleaners can be used before almost every conceivable metal finishing operation at one stage or another; they can be used by spray, by immersion, by manual application or by all three, or maybe by two out of the three methods. They can come as powders or as made-up liquids. They may be single or multipack, to be used as supplied or at a range of dilutions. They may require high temperatures or work successfully at ambient temperature. They may be suitable for cleaning one metal only or have multimetal capability. The user thus has an immense range from which to choose.

Consideration will first be given to the inorganic species used to produce the base material. The pH values of several commonly used materials are shown in [Table 1](#). Hydroxides are the simplest, strongest alkalis and most commonly used. A major effect of hydroxides in cleaning is saponification: the conversion of certain oils and greases to water-soluble soap-type materials.

Beside the benefits of hydroxides must be placed certain disadvantages:

1. The possible passivation of iron and steel surfaces; this can be a problem prior to chemical conversion coatings.

2. The soaps produced by saponification may give excessive foam during spray cleaning or react with hard-water salts to form scum and scale.
3. Amphoteric metals, such as zinc and aluminum, can be attacked (i.e., corroded) more than is desirable.
4. Powder products formulated with too much hydroxide can be hygroscopic and thus tend to form solid blocks in storage rather than remaining as free-flowing powders.
5. Spray cleaners based on hydroxide can pick up carbon dioxide from the atmosphere and such carbonated solutions become less effective.

Carbonates and bicarbonates are used as lower alkalinity adjuncts or substitutes for hydroxide and are more resistant to carbonation during spraying than hydroxide-only solutions. Powder products blended with light sodium carbonate are much less hygroscopic and the carbonate can be a useful 'carrier' for liquid additives, such as surfactants and solvents.

Silicates can offer an almost complete cleaning system on their own. Sodium silicate, the most commonly used of these materials, has a high enough pH value to cause saponification on its own and the anion formed gives a certain degree of detergency and inhibition. Thus, silicates are often found in multimetal cleaners. Light metals, such as zinc and aluminum will generally not be attacked if the silicate level is sufficiently high and the free hydroxide level sufficiently low. However, cleaners containing silicate can cause problems. They should not be used prior to an alkaline process on aluminum, owing to the formation on the surface of alkali-insoluble aluminum silicate. Cleaners containing silicates can also cause problems if used prior to some surface-sensitive treatments, such as use of zinc phosphating solutions.

Other common ingredients of alkaline cleaners include phosphates, which have both detergent and dispersive properties; also, the polyphosphates have water softening capabilities. In addition, borates are often the base for light-duty cleaners, because of their inhibiting action and less alkaline pH. They can also be used, to a certain extent, as a substitute for phosphates when a phosphate-free product is required. The organic acid salts, such as EDTA and heptonate, are included for water softening properties and to assist in the removal of solid particles. Gluconate and heptonate, in particular, are effective in the highly alkaline solutions used for etching aluminum and prevent the precipitation of aluminum hydroxide scale and sludge.

Surfactants are probably the materials which most affect the performance of alkali cleaners. Surfactants

**Table 1** pH values of selected alkalis as 1 wt% solution at 50°C

<i>Alkali</i>	<i>pH</i>
NaOH	12.7
Na <sub>2</sub> CO <sub>3</sub>	11.3
Na <sub>2</sub> SiO <sub>3</sub>	12.2
Na <sub>3</sub> PO <sub>4</sub>	11.8
Na <sub>2</sub> P <sub>2</sub> O <sub>7</sub>	10.6
Na <sub>5</sub> P <sub>3</sub> O <sub>10</sub>	9.8
Na <sub>2</sub> B <sub>4</sub> O <sub>7</sub>	9.3
NaC <sub>7</sub> H <sub>13</sub> O <sub>8</sub>	7.8

are chemicals that modify the solubility of various materials in, and their surface affinity for, oil and water. The diverse composite which makes up the surface of a metal object must be fully wetted out if the cleaner is to perform properly. Surfactants lower the surface tension to allow wetting out to occur. Oils and greases must either be dissolved off the surface or lifted from it; surfactants assist in both areas.

There are four broad categories of surfactant on the basis of the charge associated with the active part

**Figure 1** Common surfactants of each main category.

of the molecule (typical examples of each are given in [Figure 1](#)):

1. cationic, where the residual charge is positive;
2. anionic, where the residual charge is negative;
3. amphoteric, where there exists both positive and negative charge centers;
4. nonionic, where there is no residual charge.

Care must be taken with some surfactant-containing cleaners not to exceed certain temperature and concentration limits. Thus, it is not always true that the hotter and more concentrated the solution, the better the cleaning. Many commonly used surfactants have limited solubility in alkali and become less soluble as the alkalinity, ionic strength, and temperature rise. A point can, therefore, be reached when the surfactants come out of solution and, in immersion cleaning especially, performance will suffer drastically. Similarly, some spray cleaners are designed to work above a certain minimum temperature and strength. In this case, a surfactant is designed to come out of solution to act as a defoamer for the system. Examples of typical simple formulations for various types of alkali cleaners are given in [Table 2](#).

#### 4.01.2.5 Acid Pickling of Ferrous Materials

The hot rolling of steel produces a surface layer of complex oxides known as 'millscale.' It is unstable and must be removed prior to painting if reliable performance is to be obtained. Removal of millscale may be accomplished by a variety of methods but it is traditionally removed by pickling in strong acid containing one or more corrosion inhibitors.

##### 4.01.2.5.1 Formation of millscale

When mild steel is heated in air an oxide or scale will form on the steel surface. This scale consists of three well defined layers, whose thickness and composition depend on the duration and temperature of heating. In general, the layers, from the steel base outwards,

**Table 2** Typical formulations for alkali cleaners

Constituent			Composition (%)		
NaOH	20	60	20	0	0
Na <sub>2</sub> SiO <sub>3</sub>	50	20	40	60	0

Surfactant	5	5	3	5	2
Substrate application	Steel immersion	Steel electrocleaning	Zinc electrocleaning	Multimetal immersion	Aluminium spray

comprise a relatively thick layer of wüstite, the composition of which approximates to the formula  $\text{FeO}$ , a layer of magnetite ( $\text{Fe}_3\text{O}_4$ ), and a thin layer of hematite ( $\text{Fe}_2\text{O}_3$ ).

When the steel is rapidly cooled, the thickness and composition of these layers remain more or less unchanged, but when it is slowly cooled through  $575^\circ\text{C}$  the scale becomes enriched in oxygen and the remaining wüstite layer breaks down to some extent into an intimate mixture of finely divided iron and magnetite.<sup>1</sup> Holding the temperature between  $400$  and  $575^\circ\text{C}$  causes the iron particles to agglomerate and the scale becomes further enriched in oxygen. As wüstite is unstable below  $575^\circ\text{C}$ , scales produced at temperatures lower than this contain magnetite and hematite only. In addition, the scales are often cracked and porous. This is due to the difference in contraction between scale and metal on cooling and to the change in volume when the metal is oxidized.

#### 4.01.2.5.2 Mechanism of scale removal

When steel that has been slowly cooled through  $575^\circ\text{C}$  is immersed in mineral acid, the acid penetrates through the cracks and pores in the upper layers of scale and rapidly attacks the oxide layers (Figure 2). The iron, being anodic, dissolves to form ferrous ions and the magnetite, being cathodic, is reduced, forming more ferrous ions. As the three constituents of these cells are good electrical conductors, their resistance is sufficiently small so that the rate of dissolution is largely governed by the rate at which acid diffuses in through the cracks and the rate at which spent acid diffuses out through them. A similar but slower action occurs between the

exposed metal and the magnetite and hematite layers which have not been detached.

The mechanisms of oxide dissolution and scale removal have been widely studied and have been thoroughly reviewed by Frenier and Growcock,<sup>2</sup> who concluded, in agreement with others,<sup>3</sup> that oxide removal from the surface of steel occurs predominantly by a process of reductive dissolution, rather than by chemical dissolution, which is slow in mineral acids. In this process the reduction of the ferric components of the scale is coupled to oxidation of the base metal, both reactions yielding ferrous species readily soluble in the acid. For magnetite the processes are:

1.  $\text{Fe}_3\text{O}_4 + 8\text{H}^+ + 2\text{e}^- = 3\text{Fe}^{2+} + 4\text{H}_2\text{O}$
2.  $\text{Fe} = \text{Fe}^{2+} + 2\text{e}^-$

Scale removal is also assisted by the dissolution of the underlying metal by normal acid corrosion processes, which undermines the scale, and by the physical effect of hydrogen gas evolved in this latter reaction.

In general there does not appear to be any direct correlation between the rate of the chemical dissolution of oxides and the rate of scale removal, although most work on oxide dissolution has concentrated on magnetite. For example, Gorichev and coworkers have studied the kinetics and mechanisms of dissolution of magnetite in acids<sup>4,5</sup> and found that it is faster in phosphoric acid than in hydrochloric, while scale removal is slower in the former. Also, ferrous ions accelerate the dissolution of magnetite in sulfuric, phosphoric and hydrochloric acids, whereas the scale removal rate is reduced by the addition of ferrous ions. These observations appear to emphasize the importance of reductive dissolution and undermining in scale removal, as opposed to direct chemical dissolution.

As further confirmation of this Rozenfeld<sup>3</sup> has reviewed Russian work on this subject and reports that in pickling with sulfuric acid the amount of acid used in scale dissolution is only about one-tenth that consumed by the dissolution (corrosion) of the underlying metal. However, in hydrochloric acid the direct scale dissolution occurs to a much greater degree, and is responsible for about 40% of the acid consumption.

A mechanism such as that given above provides explanations for the known effects of many process variables. The reductive dissolution and undermining processes require access of the acid to the metal surface, hence the benefits obtained by the deliberate introduction of cracks in the oxide by cold-working prior to pickling. Also the increase in pickling rate with agitation or strip velocity can be explained in

**Figure 2** Mechanism of scale removal with acid: (a) high temperature scale and (b) low-temperature scale.

terms of the avoidance of acid depletion at the oxide–solution interface.

#### 4.01.2.5.3 *Hydrogen embrittlement*

Although the majority of the hydrogen produced on the cathodic areas is evolved as gas and assists the removal of scale, some of it diffuses into the steel in the atomic form and can render it brittle. Hardened and higher carbon ferritic steels are particularly susceptible to this hydrogen embrittlement and cracks may appear during pickling. Austenitic steels, however, are much more resistant to embrittlement because of the lower diffusivity of hydrogen in the face-centered cubic lattice. Certain impurities (e.g., arsenic, sulfur, antimony, etc.) promote the dissolution of hydrogen into the metal (or inhibit the hydrogen recombination reaction generating hydrogen gas, which amounts to the same thing). Consequently, this increases the quantity of hydrogen that diffuses into the steel and the consequent risk of embrittlement. Several theories of the mechanism of embrittlement have been put forward<sup>6,7</sup> and these are discussed in more detail elsewhere in this volume.

As well as causing brittleness, absorbed gas may combine to form molecular hydrogen on the surface of inclusions and voids within the steel. Thus a gas pressure is set up in the voids and this may be sufficient to cause blisters to appear either during pickling or during subsequent processing such as hot-dip galvanizing. The embrittlement effect can be largely removed by heat treatment of the steel at 150–200 °C, but even then the original ductility may not be entirely restored. In estimating the degree of embrittlement, the temperature and rate of testing have an important effect. Thus the embrittlement tends to disappear at very low and very high temperatures and is reduced at high strain rates.

#### 4.01.2.5.4 *Pickling of alloy steels*

The furnace scales which form on alloy steels are thin, adherent, complex in composition, and more difficult to remove than from nonalloy steels. Several mixed acid pickles have been recommended for stainless steel, the type of pickle depending on the composition and thickness of the scale.<sup>8</sup> For lightly-scaled stainless steel, a nitric–hydrofluoric acid mixture is suitable, the ratio of the acids being varied to suit the type of scale. Strict chemical control of this mixture is necessary, as it tends to pit the steel when the acid is nearing exhaustion. For heavy scale, two separate pickles are often used. The first conditions the scale and the second removes it. For example, a sulfuric–hydrochloric acid mixture is recommended

as a scale conditioner on heavily scaled chromium steels and a nitric–hydrochloric acid mixture for scale removal. A ferric sulfate–hydrofluoric acid mixture has advantages over a nitric–hydrofluoric acid mixture in that the loss of metal is reduced and the pickling time is shorter, but strict chemical control of the bath is necessary.

Electrolytic pickling of stainless steel in 5–10% (w/v) sulfuric acid at 50 °C can be used for removing the majority of the scale. The strip is first made anodic, when a little metal dissolves, and then cathodic, when the evolved hydrogen removes the loosened scale. To complete the pickling, a nitric plus hydrofluoric acid dip is given for austenitic steels and a nitric acid dip for ferritic steels.

The chromium-containing oxides on stainless steels are more resistant to reductive dissolution and harder to remove than oxides on mild steel. Typically mixed acids and multistage treatments are used and many formulations have been reported.<sup>9</sup> Scale conditioning can be carried out in acids, in molten salts (e.g., sodium hydroxide plus sodium nitrate) or in alkaline solutions (e.g., alkaline permanganate). Scale removal can be obtained with a variety of acids, the commonest being a nitric/hydrofluoric mixture. Rozenfeld<sup>3</sup> also reports effective pickling with ferric sulfate plus sulfuric acid mixtures and considers that the effect of the ferric ions is to speed up the dissolution of the underlying metal. Organic acids, such as citric acid, also have a role in the cleaning of lightly corroded alloy steels.<sup>10</sup>

#### 4.01.2.5.5 *Pickling inhibitors*

##### *Organic inhibitors*

During the pickling of scaled steel, the thinner and more soluble scale is removed before the thicker and less soluble scale. Consequently, some exposed base metal is attacked before the pickling operation is complete. In order to reduce this acid attack to a minimum, corrosion inhibitors are used. Although an effective inhibitor reduces acid attack, it does not prevent the attack of oxidizing agents on the exposed base metal. Thus, the ferric ions resulting from the gradual dissolution of the detached magnetite and hematite may, even in the presence of an inhibitor, attack the exposed steel causing pitting.

Clearly, the selected inhibitor should not decompose during the life of the pickle nor decrease the rate of scale removal appreciably. Some highly efficient inhibitors, however, do reduce pickling speed a little. It would be expected that as the hydrogen evolution is reduced the amount of hydrogen absorption and

embrittlement would also be reduced. This is not always the case; thiocyanate inhibitors, for example, actually increase the absorption of hydrogen.

Many organic substances soluble in acid or colloidal-dispersible have been shown to have inhibiting properties. The most effective types contain a non-polar group such as a hydrocarbon chain and a polar group such as an amine. They contain oxygen, nitrogen, sulfur, or other elements of the fifth and sixth groups of the Periodic Table. They include alcohols, aldehydes, ketones, amines, proteins, amino acids, heterocyclic nitrogen compounds, mercaptans, sulfoxides, sulfides, substituted ureas, thioureas, and thiazoles.

The efficiency of an inhibitor ( $I$ ) under a given set of conditions can be expressed by the ratio of the decreased corrosion rate as a function of the original uninhibited corrosion rate (as a percentage):

$$I = \frac{(\text{Uninhibited corrosion rate} - \text{Inhibited corrosion rate})}{\text{Inhibited corrosion rate}} \times 100\%$$

In general the efficiency increases with an increase in inhibitor concentration; typically an effective inhibitor gives >95% inhibition at a concentration of 0.01 wt% and ~90% at ~0.005 wt%. Provided the inhibitor is stable, increase in temperature usually increases the efficiency although the actual acid attack may be greater. A change in acid concentration, or in type of steel, may also alter the efficiency. Thus, the conditions of a laboratory determination of efficiency should closely simulate the conditions expected in commercial practice.

Figure 3 shows the relationship between efficiency and concentration of some thiourea derivatives and gelatin in the pickling of cold-reduced and annealed strip in 6 wt% sulfuric acid at 85 °C. The thiourea derivatives, diluted with sodium chloride, gelatin and a wetting agent, are used commercially. Mono- and di-*O*-tolyl thioureas are stable in this pickle for at least 50 h, but diphenyl thiourea and gelatin decompose after 4 or 5 h.

The principles behind the selection of effective inhibitors for steel in the various acids have been reviewed by Schmitt<sup>11</sup> and Gardner.<sup>12</sup> The selection of an inhibitor is dependent on both the metal and the acid. For steel, in general, nitrogen-based inhibitors (e.g., amines and heterocyclic compounds) are used in hydrochloric acid, whereas sulfur-containing ones (e.g., thiourea and its derivatives) find more favor in sulfuric acid.

Given the reductive dissolution process involved and the contributions from undermining and

**Figure 3** Relationship between % inhibitor efficiency and inhibitor concentration in 6 wt%  $\text{H}_2\text{SO}_4$ : (a) di-*o*-tolyl thiourea; (b) mono-*o*-tolyl thiourea; (c) commercial inhibitor containing 20% di-*o*-tolyl thiourea; (d) commercial inhibitor containing 20% diphenyl thiourea; and (e) gelatin.

hydrogen evolution in scale removal, inhibitors might be expected to affect the rate of this removal. Also, if the inhibitor adsorbs on the oxide surface then the rate of chemical dissolution of the oxide may be affected. Experimental evidence suggests that these effects may occur, depending on the acid and the inhibitor. Cumper<sup>13</sup> has shown that pyrrole and indole can increase the rate of dissolution of magnetite in hydrochloric acid. It has been reported<sup>14</sup> that commercial amine-based inhibitors can either increase or decrease the rate of scale removal in the same acid. Other reports suggest that the presence of inhibitor has little effect on scale removal rate in hydrochloric acid but markedly decreases it in sulfuric acid. One area that has not been widely studied is the effectiveness of inhibitors on scaled surfaces, but there is experimental evidence that the presence of magnetite scales can significantly affect the performance of nitrogen-based inhibitors in alkaline solutions used for chemical cleaning.

#### Inorganic inhibitors

Inorganic inhibitors are salts of metals having a high hydrogen overvoltage, for example, antimony and arsenic salts. The inhibiting action is associated with the formation of a coating of the metal, which, being cathodic to the steel and having a high hydrogen overvoltage, prevents the discharge of hydrogen ions and so stops the dissolution of the steel. These inhibitors are seldom used in commercial practice, but antimony chloride dissolved in concentrated hydrochloric acid is used in the laboratory for stripping

deposits of zinc, cadmium, tin, and chromium from steel, and with the addition of stannous chloride for removing scale and rust.<sup>15</sup>

#### 4.01.2.6 Acid Pickling of Nonferrous Metals

Although less common, acids are also used for the removal of oxide and scale from nonferrous metals and alloys. Table 3 summarizes a number of pickling solutions for selected materials.

##### 4.01.2.6.1 Electrochemical cleaning

A significant increase in immersion cleaning performance can be achieved by local agitation caused by vigorous gas evolution on the surface of the workpiece. Thus, the use of an applied cathodic voltage evolves hydrogen, which provides a 'scrubbing' action, greatly enhancing the cleaning process. However, during cathodic cleaning any dissolved metal ions in solution will tend to plate-out on the metal surface, so the work will normally be given a short anodic cycle at the end of the cleaning time to dissolve this contamination. Also, periodic reverse cathodic-anodic cycling is another way of achieving the same effect. Anodic cleaning can also be performed as a small fraction of the metal is dissolved, thereby simultaneously removing any contamination; however, this should be done with care, as otherwise the workpiece may be destroyed.

For electrocleaning, care must be taken that a solution of sufficiently high conductivity is used to prevent solution voltage drops and 'burning' of workpieces in high current density areas. Clearly, excessively high anode current densities should be avoided as these will cause excess corrosion/dissolution of the

workpiece. Care must also be taken during cathodic cleaning of steel alloys as hydrogen embrittlement, which must always be considered a risk during cathodic cleaning, must be either avoided or allowed for.

#### 4.01.2.7 Ultrasonic Cleaning

Another method for introducing mechanical action into immersion cleaning is by the use of ultrasonic agitation. Here, a high frequency vibration is imparted to the solution. At the surface to be cleaned, minute bubbles are formed by local cavitation of the fluid. When they collapse, they impart a high degree of local agitation, thereby efficiently removing any surface contamination.

#### 4.01.3 Mechanical Cleaning

##### 4.01.3.1 Flame Cleaning

Now little used as a preparatory method, flame cleaning is a process whereby an intensely hot flame is played on the surface of the steel. In theory, differential expansion causes millscale to detach. In practice, there is evidence that the treatment may not remove thin, tightly adhering millscale. Also, steel less than 5 mm thick can buckle. Finally, the process can 'burn in' chemicals deposited on the surface, causing premature paint failure.

##### 4.01.3.2 Manual Cleaning

The term encompasses all manual and mechanical methods of cleaning other than blast-cleaning, for example abrasive discs, wire brushes, scrapers, vibratory needle guns and chipping hammers are all

**Table 3** Pickling solutions for nonferrous metals

<i>Metal</i>	<i>Acid</i>	<i>Temperature</i>	<i>Time</i>
Copper and brass (60–90% Cu, 10–40% Zn)	7–25% (w/w) H <sub>2</sub> SO <sub>4</sub> or 15–25% (w/w) HCl	15–60 °C	1–10 min
Aluminium bronze (82–95% Cu, 5–10% Al, 0–5% Fe, 0–5% Ni)	Scale conditioned with 10% (w/w) NaOH followed by H <sub>2</sub> SO <sub>4</sub> or HCl as above	15 °C	1–3 min
Copper–silicon alloys (96–97% Cu, 1–3% Si)	7–25% (w/w) H <sub>2</sub> SO <sub>4</sub> + 1–3% (w/w) HF	75 °C	2–5 min
Nickel–copper alloys (55–90% Cu, 10–30% Ni, 0–27% Zn)	10% (w/w) HCl + 1.5% (w/w) CuCl <sub>2</sub>	15 °C	1–5 min
Nickel–chromium alloys (35–80% Ni, 16–20% Cr, 0–45% Fe, 0–2% Si)	10% (w/w) HCl + 1.5% (w/w) CuCl <sub>2</sub>	80 °C	30 min
Aluminium alloys (0–10% Cu, 0–30% Mg, 0–6% Zn, 0–12% Si)	Scale conditioned with 20% NaOH + 5% (w/w) KMnO <sub>4</sub> followed by 20% (w/w) HNO <sub>3</sub> + 4% (w/w) HF	100 °C	1–2 h
Magnesium alloys (0–10% Al, 0–3% Zn, 0–0.2% Mn)	25% (w/w) H <sub>2</sub> SO <sub>4</sub> + 5% (w/w) CrO <sub>3</sub>	50 °C	5–30 min
	40% (w/w) HNO <sub>3</sub> + 1–5% (w/w) HF	65 °C	20 min
	10–20% (w/w) CrO <sub>3</sub> + 3% (w/w) H <sub>2</sub> SO <sub>4</sub>	15 °C	1–5 min
		100 °C	1–30 min
		25 °C	15 s

available. Manual cleaning removes neither tightly adhering millscale nor deep-seated rust from pits. None the less, it is often used for maintenance work or for the preparation of new steelwork to be exposed in nonaggressive conditions. Manual cleaning is rarely used in conjunction with, as it is inappropriate for, high-performance long-life systems, for example, two-pack chemically curing coatings which require a high standard of blast cleaning.

#### **4.01.3.3 Abrasive Blast Cleaning**

Abrasive blast cleaning uses the action of abrasive particles suspended in a fluid (e.g., air or water) in order to remove surface contamination by mechanical action. Thus, abrasive particles are directed at high velocity against the blasted surface by means of compressed air, high-pressure water, or centrifugal force from an impeller wheel. As the surface removal rate can be controlled by choice of equipment, abrasive grit and blast parameters, all kinds of surfaces may be prepared including heavily rusted steel and concrete, as well as lightly contaminated surfaces.

##### **4.01.3.3.1 Surface finish**

Surface 'finish' commonly means surface cleanliness. It is important to remember that cleanliness refers not only to the degree of residual rust present, but also to the level of surface chemical contamination from soluble salts and from condensed moisture layers, all of which will detrimentally affect coating adhesion and ultimate performance.

##### **4.01.3.3.2 Surface profile**

Blast-cleaning produces a roughened surface, the size and nature of which is largely determined by the type and size of the abrasive used. The nature of the profile is important, especially for application of organic coatings (paints) and for thermally sprayed metal coatings. This is because the profile acts to aid the mechanical 'keying' of the coating to the surface and, hence, greatly increases coating adhesion. Likewise, the peak-to-trough profile roughness should not be excessive as this causes rogue peaks from the substrate to penetrate beyond the coating surface. Finally, profiles should be relatively open as excessively compressed surfaces will contain pores and defects underneath the coating that can act as reservoirs for chemical contamination and certainly will prevent coating penetration to the complete surface.

#### **4.01.3.4 Ultrahigh Pressure Water Jetting**

Water jetting is a convenient method for light cleaning and washing of surfaces. However, if the pressure of the water is increased significantly, the fluid becomes capable of removing, with high efficiency, relatively loosely adherent materials on a surface, including organic coatings. Water jetting also leaves surfaces relatively free of soluble salt contamination, which is a considerable advantage. Because of the kinetic energy of the water droplets on hitting the blasted surface, ultrahigh pressure water jetting leaves a dry, slightly warm surface that is free of dust and which dries relatively quickly; therefore, repainting can be carried out without significant delay.

The recent trend is to increase pressures as less volume of water is used. Thus, ultrahigh pressure (>170 MPa) water jetting equipment is becoming preferred as disposal costs for contaminated water are reduced. Water jetting cannot change an existing surface profile; hence if this is inadequate, abrasive blasting is to be preferred. However, for surfaces that have an adequate abrasive blast profile, it is sufficient to merely remove the defective coating and water jetting can be a highly economical option to achieve this end.

#### **4.01.3.5 Health, Safety, and the Environment**

In all surface preparation methods, including chemical and mechanical cleaning options, health, safety and environmental concerns are essential. Organic solvents are toxic and clearly have high VOC levels while aqueous alternatives may still possess significant organic content; in both cases operator protection and chemical disposal need to be addressed adequately. Organic-free chemical cleaners are frequently highly corrosive (acidic or alkaline), and also require correct neutralization and disposal procedures. Mechanical cleaning operations contain their own danger, not the least of which is the safety of the operator; to this end correct operator training, especially for abrasive and water jetting operations, is essential. Finally, waste abrasive grit and paint are frequently contaminated by toxic heavy metals previously used as corrosion inhibitive pigments (i.e., lead, chromium, etc). Removal and disposal of such materials often require a special license and certainly require great care and attention to detail.

#### 4.01.4 Standards

Generally standards for surface preparation, especially for surfaces subsequently to be painted, use visual comparisons. In all such standards, some caution should be exercised because the color reproduction may vary from one copy to another.

Standards for degrees of surface rusting are described in ISO 8501-1 as follows:

- (a) Steel surface largely covered with adhering mill scale, but little if any rust.
- (b) Steel surface which has begun to rust and from which mill scale has begun to flake.
- (c) Steel surface on which the mill scale has rusted away or from which it can be scraped, but with slight pitting visible under normal vision.
- (d) Steel surface on which the mill scale has rusted away and on which general pitting is visible under normal vision.

Surface rust and millscale must be removed before surface protection is applied. Where this is done by abrasive blasting, standards of surface cleanliness are also described in ISO 8501-1 and are on the basis of the original Swedish SIS 05 5900:

- Sa 1: Light blast cleaning.
- Sa 2: Thorough blast cleaning.
- Sa 2½: Very thorough blast cleaning.
- Sa 3: Blast cleaning to visually clean steel.

The minimum standard that is normally accepted for organic coating of steel structures is the Sa 2½ grade, which is generally achievable in the field using hand-held equipment. Sa 3, which is effectively blasting to white metal, can be achieved using modern automated shot-blast plant under factory conditions.

### 4.02.1 Introduction

Phosphate treatments are readily adaptable to production requirements for articles of all sizes, and for large or small numbers. Mild steel sheet is the material most frequently subjected to phosphate treatment, but a great variety of other ferrous surfaces is also processed. Examples include cast-iron plates and piston rings, alloy steel gears, high-carbon steel cutting tools, case-hardened components, steel springs and wire, powdered iron bushes and gears, etc. Phosphate treatments designed for steel can also be used for the simultaneous treatment of zinc die-castings, hot-dipped zinc, and zinc-plated articles. However, if there is a large quantity of these nonferrous articles, it is often more economical to phosphate them without the steel. Aluminum articles may also be phosphated; however, these require somewhat different bath chemistries.

The usual method of applying phosphate coatings is by immersion, using a sequence of tanks that includes degreasing and phosphating stages, with their respective rinses. The treatment time ranges from 3 to 5 min for thin zinc phosphate coatings and up to 30–60 min for thick zinc, iron, or manganese phosphate coatings. The accelerated zinc phosphate processes lend themselves to application by power

spray, and the processing time may then be reduced to 1 min or less. Power spray application is particularly advantageous for mass-production articles such as motorcars and refrigerators, as the conveyor can run straight through the spray tunnel, which incorporates degreasing, rinsing, phosphating, rinsing, and drying stages. Flow-coating and hand spray-gun application are sometimes employed when a relatively small number of large articles have to be phosphated.

## 4.02.2 Phosphate Coating Formation

### 4.02.2.1 Deposition Mechanism

All conventional phosphate coating processes are based on dilute phosphoric acid solutions of iron, manganese, and zinc dihydrogen phosphates either separately or in combination. The free phosphoric acid in these solutions reacts with the iron surface undergoing treatment in the following manner<sup>1</sup>:

Thus, ferrous dihydrogen phosphate is produced and hydrogen is liberated. Local depletion of phosphoric acid occurs at the metal-solution interface. As the dihydrogen phosphates of iron, manganese, and zinc dissociate readily (i.e., are soluble) in aqueous solution, the following reactions take place:

The neutralization of free phosphoric acid by reaction [1] alters the position of equilibrium of equations [2]–[4] towards the right and thereby leads to the deposition of the sparingly soluble hydrogen phosphates and insoluble phosphates on the metal surface.

As reaction [1] takes place even when the phosphating solution contains zinc or manganese phosphate with little or no dissolved iron, it will be seen that the simple (or nonaccelerated) phosphate treatment gives coatings that always contain iron phosphate derived from the ferrous parts being processed. After prolonged use, a manganese phosphate bath often contains more iron in solution than manganese and produces coatings with an iron content 2–3 times that of manganese.

The relation between free phosphoric acid content and total phosphate content in a processing bath, whether based on iron, manganese, or zinc, is very

important; this relation is generally referred to as the acid ratio. An excess of free acid will retard the dissociation of the dihydrogen and hydrogen phosphates and hinder the deposition of the insoluble phosphate coating; sometimes excessive loss of metal takes place and the coating is loose and powdery. When the free acid content is too low, dissociation of phosphates takes place in the solution as well as at the metal/solution interface and leads to precipitation of insoluble phosphates as sludge. Nonaccelerated processes operated near boiling generally work best with a free-acid titration between 12.5% and 15% of the total acid titration.

A zinc phosphate solution tends to produce coatings more quickly than iron or manganese phosphate solutions, and dissociation of zinc dihydrogen phosphate proceeds rapidly through reaction [2] to [3] or directly to zinc phosphate via reaction [4]. Even so, a processing time of 30 min is usual with the solution near boiling. Another factor in the initiation of the phosphate coating reaction is the presence in the processing solution of phosphate, either as a colloidal suspension or as fine particles.<sup>2</sup> This effect is most apparent in zinc phosphate solutions, which produce good coatings only when turbid. The zinc phosphate particles can be present to a greater extent in cold processing solutions and may act as nuclei for the growth of many small crystals on the metal surface, thereby promoting the formation of smoother coatings.

Similarly, the ferric phosphate sludge formed during the processing of steel in a zinc phosphate solution can play a useful part in coating formation.<sup>3</sup> The solubility of ferric phosphate is greater at room temperature than at elevated temperatures, and is increased by the presence of nitrate accelerators. To allow for saturation at all temperatures, it is desirable always to retain some sludge in the processing bath. Coatings with optimum corrosion resistance are produced when the temperature of the bath is rising and causing supersaturation of ferric phosphate.

With zinc/iron/phosphate/nitrate baths, the iron content of the coating comes predominantly from the processing solution and very little from the surface being treated.<sup>4</sup> This greatly diminished attack on the metal surface by accelerated baths has a slight disadvantage in practice in that rust is not removed, whereas the vigorous reaction of the nonaccelerated processes does remove light rust deposits. The solution of iron represented in eqn [1] takes place at local anodes of the steel being processed, while discharge of hydrogen ions with simultaneous dissociation and deposition of the metal phosphate takes place at the

local cathodes.<sup>1</sup> Thus, factors that favor the cathode process will accelerate coating formation and, conversely, factors favoring the dissolution of iron will hinder the process.

Application of a cathodic potential to the treated surface exerts an accelerating action, as the reaction at all cathodic areas is assisted and the formation of a phosphate layer is speeded accordingly. Conversely, an anodic potential results in the dissolution of iron at local anodes and hinders phosphate coating formation. An oxidizing agent acts as an accelerator by depolarization of the cathodes, raising the density of local currents so that rapid anodic passivation of active iron in the pores takes place. This inactivation of local anodes favors the progression of the cathodic process. The accelerating effect of alternating current is explained by the practical observation that the cathodic impulse acting protectively greatly exceeds in its effect the anodic impulse which dissolves iron. In a similar manner, the electrolytic pickling of iron with alternating current can dissolve iron at a slower rate than when no current is used.

Reducing agents have the same ultimate effect as cathodic depolarization in that they convert anodic regions into cathodic regions and increase the ratio of cathodic to anodic areas. Nitrogenous organic components such as toluidine, quinoline, aniline, etc. all act as inhibitors to the anodic reaction between metal and acid and thereby favor the cathodic reaction and accelerate the process.

#### 4.02.2.2 Accelerators

The majority of phosphate processes in use are 'accelerated' to obtain shorter treatment times and lower processing temperatures. The most common mode of acceleration is by the addition of oxidizing

agents such as nitrate, nitrite, chlorate, and hydrogen peroxide. By this means, a processing time of 1–5 min can be obtained at temperatures of 45–70 °C. The resultant coatings are much smoother and thinner than those from nonaccelerated processes, and, while the corrosion resistance is lower, they cause less reduction of paint gloss and are more suited to mass-production requirements.

The presence of nitrate as accelerator has a pronounced effect on the amount and composition of gas evolved from the work being treated<sup>1</sup> (Table 1). It will be observed that hydrogen evolution drops to a very low figure with the zinc/nitrate baths. The formation of nitrite arises from the oxidation of ferrous ion by nitrate leading to ferric ions, which will then deposit out as ferric phosphate:

In acid solution, the nitrite ion acts as an oxidizing agent. A slight degree of acceleration can be obtained by introducing traces of metals which are more noble than iron, for example nickel, copper, cobalt, and silver. These metals are deposited electrochemically over the iron surface undergoing treatment, thereby providing more active cathodic centers and promoting phosphate deposition. This method of acceleration has the disadvantage of leaving minute particles of the noble metal in the coating, and, in the case of copper, this can seriously inhibit the drying of some types of paint coatings.

#### 4.02.3 Nature of Coatings

##### 4.02.3.1 Types of Coating

Although there is a limited number of phosphate coating types, there are many specific bath compositions

**Table 1** Amount and composition of the gases evolved on phosphating of 1 m<sup>2</sup> of sheet metal for deep drawing

Phosphate solution	Pointage <sup>a</sup>	Time (min)	Amount of gas (cm <sup>3</sup> m <sup>2</sup> )	H <sub>2</sub> (%)	N <sub>2</sub> (%)	O <sub>2</sub> (%)	N <sub>2</sub> O + NO (%)
Manganese phosphate	30	60	7000	87.5	11.4 <sup>b</sup>	1.1	–
Zinc phosphate	40	30	2540	92.7	6.4 <sup>b</sup>	0.9	–

Zinc phosphate containing 1.5–2 g l <sup>-1</sup> iron (accelerated with nitrate)	70	5	85	32.1	57.0	1.6	9.3

<sup>a</sup>A measure of the total of a phosphating solution, as indicated by the number of ml of 0.1 N sodium hydroxide (4.0 g l<sup>-1</sup>) needed to neutralise 10 ml of the phosphating solution to phenolphthalein.

<sup>b</sup>Presumably from anrides present in the steel.

that have been formulated for optimization of particular applications and processes.<sup>5</sup> Lightweight amorphous iron phosphates provide excellent paint adhesion and are of low cost; however, the corrosion resistance is relatively poor. Lightweight (microcrystalline) zinc phosphate coatings offer higher corrosion resistance while still retaining very good adhesion for organic coatings. Heavy macrocrystalline zinc phosphates are used in applications such as fastener coatings or wire and tube drawing aids. Where used in this fashion, the coating provides excellent adhesion and a slightly porous surface that can act as a reservoir for drawing lubricants such as soaps and/or oils. Likewise, heavy-weight manganese-iron phosphates and calcium-zinc phosphates may be used to reduce galling on mating surfaces such as valve train components or hypoid gears. These coatings have good oil absorbing properties and provide good corrosion resistance when used with a rust-preventing oil. Military ordnance components are often finished by this method. **Table 2** provides a summary of some types and applications of phosphate coatings.

#### 4.02.3.2 Effect of Metal Surface

The state of the metal surface has a pronounced effect on the texture and nature of phosphate coating produced by orthodox processes. Heavily worked surfaces tend to be less reactive and lead to patchy coatings. Surface abrasive blasting greatly simplifies treatment and gives uniform phosphate coatings. Accidental contamination of sheet steel with lead has been shown to have an adverse effect on the corrosion resistance and durability of phosphate coatings and paint.<sup>6</sup>

Cleaning operations that make use of strong acids or strong alkalis tend to lead to the formation of

excessively large phosphate crystals which do not completely cover the metal surface and therefore show inferior corrosion resistance; this is particularly serious if rinsing is inadequate between the preparatory treatment and the phosphating. Adherent dust particles can also lead to the formation of relatively large phosphate crystals, whereas surfaces that have been wiped beforehand show much smoother and more uniform phosphate coatings.

On the other hand, the provision of vast numbers of minute nuclei assists the phosphate coating reaction to start at a multitude of centers, resulting in a finely crystalline coating. This effect can be obtained chemically by a predip in a solution of sodium phosphate containing minutely dispersed traces of titanium or zirconium salts<sup>7</sup> or in weak solution of oxalic acid. This type of predip entirely eliminates any coarsening effect due to previous treatment in strong alkalis or acids.

#### 4.02.3.3 Effect of Phosphate Solution

Improved nucleation within the phosphate solution itself can produce smoother coatings without the necessity of recourse to preliminary chemical treatment. This may be accomplished by introducing into the phosphating bath the sparingly soluble phosphates of the alkaline-earth metals or condensed phosphates such as sodium hexametaphosphate or sodium tripolyphosphate. Such modified phosphating baths produce smoother coatings than orthodox baths and are very much less sensitive to cleaning procedures.

Very thin coatings of iron phosphate can be produced by treatment with solutions of alkali-metal phosphate. These serve a useful purpose for the treatment of office furniture, toys, etc. where a high

**Table 2** Types of phosphate coating

Type	Mineral name	Formula	Coating weight ( $\text{g m}^{-2}$ )	Appearance
Lightweight iron phosphate	Vivianite	$\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$	0.3–0.9	Iridescent pink/yellow/blue to light gray
Microcrystalline zinc phosphate	Hopeite or phosphophyllite	$\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$ ; $\text{FeZn}_2(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$	1.4–2.7	Light gray
Macrocrystalline zinc phosphate	Hopeite or phosphophyllite	$\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$ ; $\text{FeZn}_2(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$	7.5–30	Light gray
Manganese iron phosphate	Hureaulite	$(\text{Mn,Fe})_5(\text{PO}_4)_4 \cdot 4\text{H}_2\text{O}$	7.5–30	Dark gray to black
Calcium zinc phosphate	Scholzite	$\text{CaZn}_2(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$	1.6–6.5	Light gray

degree of protection is not required, and also as a base for phenolic varnishes or resin varnishes requiring high temperature curing, for example, at over 200 °C. The coating is of heterogeneous nature and contains less than 35% iron phosphate ( $\text{FePO}_4 \cdot 8\text{H}_2\text{O}$ ) with the remainder probably  $\gamma\text{-Fe}_2\text{O}_3$ .<sup>8</sup>

Thin phosphate coatings can be formed by application of phosphoric acid solution alone, that is, not containing metallic phosphates, to a steel surface, sufficient time being allowed after application to enable complete reaction to take place. In this way, a thin film of iron phosphate can be formed. In practice, it is difficult to obtain complete conversion, and the remaining traces of phosphoric acid can cause blistering of paint coatings. This effect may be insignificant on rough, absorbent steel surfaces, for example, ship's plating, where heavy coats of absorbent paint are applied, and under these circumstances the treatment can enhance the corrosion resistance of the finishing system.

#### 4.02.3.4 Composition and Structure

The simplest phosphate coating that is formed from a solution containing only ferrous phosphate and phosphoric acid consists of dark gray to black crystals of ferrous phosphate,  $\text{Fe}_3(\text{PO}_4)_2$  and ferrous hydrogen phosphate,  $\text{FeHPO}_4$ , with a small proportion of ferric phosphate,  $\text{FePO}_4$ . Coatings formed from manganese phosphate solutions consist of  $\text{Mn}_3(\text{PO}_4)_2$ , and those from zinc phosphating solutions consist of  $\text{Zn}_3(\text{PO}_4)_2$ . With both the manganese and zinc type of coating, insoluble iron phosphates, derived from iron present in the bath, may also be present in solid solution. Iron from the surface being treated can also be present in the coating, particularly at the metal-phosphate interface. The  $\text{PO}_4^{3-}$  content of coatings may vary from 33% to 50%, whereas the theoretical  $\text{PO}_4^{3-}$  content is lowest, at 41%, in  $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$  and highest, at 63%, in  $\text{FePO}_4$ .

X-ray diffraction studies have given very good correlation between the mineral hopeite,  $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$ , and the zinc phosphate coatings that form on steel.<sup>9</sup>  $\text{Zn}_3(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$  appears in three crystal forms:  $\alpha$ -hopeite (rhombic plates),  $\beta$ -hopeite (rhombic crystals), and  $\delta$ -hopeite (triclinic crystals). Their transition points are at 105, 140, and 163 °C, respectively. It has been observed<sup>10</sup> that zinc phosphate coatings heated in the absence of air lose their corrosion resistance at between 150 and 163 °C probably due to disruption in coating integrity due to the volume changes arising from the phase change. Likewise, manganese phosphate coatings lose their corrosion

resistance at between 200 and 218 °C, where they lose between 75 and 80% of their water of hydration. It is assumed that this results in a volume decrease of the coating which causes voids and thereby lowers the corrosion resistance. Figure 1 shows the loss of water of hydration from zinc, iron, and iron-manganese phosphate coatings.

The heating of phosphate coatings in the absence of air provides conditions similar to those prevailing during the stoving of paint on phosphated articles, but in general the paint stoving temperatures and times are well below those at which damage to zinc phosphate coatings takes place. The loss of water from conventional zinc and manganese phosphate coatings heated in air is from 10 to 20% higher than the loss on heating in the absence of air. It is thought that this greater loss may be due to oxidation of the iron phosphate present in the coatings.

The most important uses for phosphate coatings entail sealing with oil or paint and it is therefore of interest to study absorption values. Table 3 compares the absorption of diacetone alcohol into coatings of widely differing thicknesses and composition; despite these differences, values of 10.5–13  $\text{g m}^{-2}$  are obtained throughout. It is therefore evident that absorption is predominantly a surface effect and not appreciably influenced by coating thickness.

**Figure 1** Effect of heating on phosphate coatings for 16 h at various temperatures, showing loss of water of hydration: (a) zinc phosphate; (b) iron phosphate, and (c) iron manganese phosphate. Reproduced from B.S.I. Phosphate Coatings (Drafting) Panel, *J. Iron Steel Inst.* 1952, 170, 13.

**Table 3** Analytical tests on industrial phosphate coatings

Process <sup>a</sup>	P	S	T	Q	V	R
Main cation in phosphate bath	Fe	Mn	Zn	Zn	Zn	Zn
Method of application	Immersion	Immersion	Spraying	Immersion	Immersion	Immersion
Duration of treatment (min)	15	30	1.5	4	5	12
Change in weight on phosphating ( $\text{g m}^{-2}$ )	-26.1	-26.4	2.61	3.37	1.63	5.87
Coating weight ( $\text{g m}^{-2}$ )	14.2	21.2	4.46	5.43	3.48	12.28
$\text{PO}_4^{3-}$ ( $\text{g m}^{-2}$ )	7.0	8.9	1.96	2.07	1.20	4.46
Moisture ( $\text{mg m}^{-2}$ )	81.5	76.1	152.2	396.6	173.9	771.7
$\text{PO}_4^{3-}$ content of coating (%)	49.0	42.0	44.0	38.0	34.0	36.0

#### 4.02.3.5 Post-phosphating Treatment: Rinses

After phosphating, thorough rinsing with water is necessary in order to remove soluble salts which would otherwise tend to promote blistering under a paint film. Care should also be taken to ensure that the water supply itself is sufficiently free from harmful salts. Experience has shown that a water supply is potentially injurious if it exceeds any one of the three following limits:

1. 70 ppm total chlorides and sulfates (calculated as  $\text{Cl}^- + \text{SO}_4^{2-}$ );
2. 200 ppm total alkalinity (calculated as  $\text{CaCO}_3$ ); and
3. a maximum of 225 ppm of (1) and (2) together.

Improved corrosion resistance and reduced tendency to blistering was traditionally obtained by treating the final rinse with chromic acid, or preferably with phosphoric and chromic acids combined. Normally, a total acid content of 0.05% was used, with higher concentrations of chromate increasing corrosion resistance. However, legislation restricting the use of chromates has now eliminated this practice. The use of demineralized water for rinsing purposes is recommended, especially before electrophoretic painting, as this practice reduces residual surface contamination. The demineralized water is generally applied by misting jets at the end of all other pretreatment stages and allowed to flow back into the last rinse tank. In certain cases, rinsing may be dispensed with after nonaccelerated phosphate treatment, but blistering of

paint due to local concentration of solution in seams and crevices may occur. Thus, it is good practice to employ rinsing, regardless of the type of phosphate process.<sup>11</sup>

#### 4.02.4 Performance

##### 4.02.4.1 Corrosion Protection

The corrosion protection provided by phosphate coatings without a sealing treatment is of a low order; their value when sealed is considerably greater. Unsealed corrosion tests are therefore of little value except perhaps for studying porosity or efficiency of coatings destined to be sealed only with oil. It is usually necessary to control the acid ratio of phosphating baths, particularly those of iron, manganese, and zinc operating near boiling point that produce heavy coatings. The best performing coatings are obtained when the free acidity is maintained between 12.5% and 15%; above this figure, coatings with progressively lower corrosion resistance are obtained. Note that heavy, that is, thicker phosphate coatings do not necessarily have better corrosion resistance than lighter coatings. Even with a single process, for example, zinc/iron/phosphate/nitrate, no consistent relationship has been found between corrosion resistance and either coating weight or weight of metal dissolved. Jaudon<sup>12</sup> tested phosphate coatings and found the salt-spray resistance, as judged by the first appearance of rust, while only a few minutes for base steel, was around a few hours for phosphated steel.

**Table 4** Typical phosphate coating processes

<i>Phosphate coating solution</i>	<i>Accelerator</i>	<i>Immersion time (min)</i>	<i>Type of coating</i>	<i>Coating weight (g m<sup>-2</sup>)</i>
Iron	None	30	Heavy	10.87–32.61
Iron/manganese	None	30	Heavy	10.87–32.61
Manganese	Nitrate	15	Heavy	8.70–32.61
Zinc	Nitrate	15	Medium	3.26–32.61
Zinc	Nitrate/nitrite or chlorate	3	Light	1.09–6.52
Sodium/ammonium	None	1–2 (spray)	Very light	0.22–0.65

Phosphating prior to painting doubled the observed time to first rusting.

Phosphate processes containing little or no oxidizing agent and based on manganese or zinc tend to accumulate iron in solution from the work being processed. With a manganese content from 0.2% to 0.5%, it is best to control the iron between 0.2% and 0.4%; a higher iron content reduces the corrosion resistance and may lead to the formation of thin powdery coatings, while a lower iron content gives soft coatings. Similarly, a zinc process operates best with 0.15–0.5% zinc and 0.4–0.5% iron. Again, with a higher iron content corrosion resistance falls off and powdery coatings may be formed, and soft coatings result from lower iron content.

Within broad limits, phosphate processes can be classified according to the main metallic radical of the processing solution and the type of accelerator used; typical processes are given in [Table 4](#). The selection of process and of coating weight is mainly dependent on the end-use of the article being processed; the general requirements for corrosion resistance and wear prevention are given in [Table 5](#).

#### 4.02.4.2 Testing

Heavy phosphate coatings are generally used as protection against corrosion in conjunction with a sealing film of oil or grease. The porosity or free pore area of these coatings should be kept to a minimum. Machu<sup>13</sup> devised a method of examination based on the quantity of electricity necessary to effect passivation of the bare steel and used this to determine the free pore area which, in the phosphate coatings tested, varied from 0.27% to 63%; however, this method is insufficiently sensitive to evaluate thin zinc phosphate coatings. A method for making rapid measurements of the electrical resistance of phosphate coatings has been described by Scott and Shreir.<sup>14</sup>

The most widely used accelerated tests are based on salt spray, whose main value is in the evaluation of

**Table 5** Typical uses of phosphate coatings on steel

<i>Coating weight (g m<sup>-2</sup>)</i>	<i>For corrosion resistance</i>	<i>For wear prevention and metal forming</i>
21.74–32.61	–	Critical cold extrusion
10.87–21.74	Military equipment, etc. requiring oil or grease finish	Normal cold extrusion 'Running in' treatment for piston rings, gears and tappets
5.43–10.87	Nuts, bolts, clips, brackets	Wire and tube drawing Sheet steel pressing

1.63–2.17	Steel drums, bicycles, office machinery	
0.22–0.65	Toys, office furniture Strip steel, for painting and forming	

the effectiveness of phosphate coatings in restricting the spread of rust from scratches or other points of damage in a paint film.<sup>15</sup> This feature is of particular interest to the automotive industry, as vehicles are often exposed to marine atmospheres and to moisture and salt when the latter is used to disperse ice and frost from road surfaces. Great care is needed in the interpretation of a salt-spray test, as it has been found to favor thin iron phosphate coatings more than is justified by experience with natural weathering. Humidity tests are generally of more practical use than salt-spray tests, particularly where painting is employed, as the thoroughness of rinsing may be checked by this means. The use of contaminated water can leave water-soluble salts in the phosphate

**Table 6** Weights of phosphate coatings

Class of phosphate process	Coating weight (g m <sup>-2</sup> )	
	Min.	Max.
A 1. Heavyweight (Mn or Fe)	7.61	–
A 2. Heavyweight (Zn)	7.61	–
B Medium weight (Zn, etc.)	4.34	–
C Lightweight (Zn, etc.)	1.09	4.34
D Extra lightweight (Fe)	0.33	1.09

Source: BS EN 12476: Phosphate conversion coatings of metals. Method of specifying requirements.

coating and lead to blistering of the paint film under humid conditions, as paint films are permeable to water vapor. Immersion in water, or subjection to high humidity in a closed cabinet, will generally show any defects of this kind within a few days.

Phosphate coating weight determinations are generally performed by dissolving the coating from weighed panels using inhibited acid (e.g., by immersion in a solution of 20 g dm<sup>-3</sup> of antimony trioxide in concentrated hydrochloric acid at a temperature of 13–21 °C. Thin iron or zinc phosphate coatings can be removed for weight determination by immersion in 5% chromic acid solution at 70 °C, but this solution should also be used only once, as the presence of more than a trace of phosphate leads to pitting of the steel and false results. Zinc phosphate coatings can be removed by immersion in 10% sodium hydroxide at boiling temperature, aided by rubbing during rinsing.

BS EN 12476 contains information on the operation of phosphate processes to obtain optimum results and on the testing of phosphate coatings.<sup>16</sup> The classification of coatings according to composition and weight is shown in Table 6. The inspection and testing includes determination of coating weight, freedom from corrosive residues as shown by a humidity test, and resistance to corrosion by salt spray. BS EN ISO 12944-1 is also a valuable source of information.<sup>17</sup>

#### 4.02.4.3 Phosphophyllite–Hopeite Ratio

There is evidence that the ratio of phosphophyllite to hopeite (the so-called P/(P + H) ratio) can be used as a predictive measure of the performance of phosphated steel when coated with cathodic electroprimer and paint.<sup>18,19,20,21</sup> In this context, P is defined as the intensity of X-rays diffracted from the (100) plane of phosphophyllite, FeZn<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub>·4H<sub>2</sub>O, and H is defined as the intensity of X-rays diffracted from the (020) plane of hopeite, Zn<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>·4H<sub>2</sub>O,

and it has been suggested that higher values of this ratio (i.e., a low volume fraction of hopeite) are synonymous with good corrosion performance.<sup>18</sup> However, other factors to be considered include the need for homogeneous phosphate layers of controlled thickness, the direct attachment of the primer to a coherent layer, and the level of interlayer cohesion within the coating. Some papers<sup>21</sup> indicate that adhesion failure results from internal fracture of the phosphate coating and that it is concentrated at the junction between a primary microcrystalline or even amorphous layer close to the metal substrate and a secondary layer exhibiting relatively coarse crystallinity. The primary layer is comprised essentially of a zinc phosphate material, and the Zn/P ratio in the retained primary layer after fracture is lower than that in the detached material, though close enough to be considered essentially similar.

Finally, it is worth noting that the quality of the steel substrate can have an effect on the corrosion resistance promoted by any subsequent treatment by phosphating and painting. Indeed, it has been reported<sup>22</sup> that interesting results are obtained when cold-rolled steel panels, with different amounts of surface contamination, are zinc phosphated, then coated with anionic or cationic electrocoat primers, and followed by a conventional filler-topcoat system. In salt-spray, scab, and filiform corrosion tests, it is apparently possible to distinguish between different surface contamination levels and primer coatings. Carbonaceous residues on the steel can have a detrimental effect, and this can be confirmed in the case of anionic primer during salt-spray tests. In the scab corrosion and filiform corrosion tests, however, anionic primer performance actually increases with surface contamination. It can be concluded that the steel condition and the type of coating affect the corrosion resistance of the entire system by inducing changes in the phosphate layer. With the current low level of surface contamination of commercial steels and the highly resistant modern coating formulations, it is suggested<sup>22</sup> that the phosphate layer is the weakest link in the entire system.

### Glossary

**Barrier anodic film** An oxide coating deliberately formed on a valve metal (commonly aluminum) that is generally relatively featureless and provides an electrical and physical barrier to the bare metal surface.

**Porous anodic film** An oxide coating deliberately formed on a valve metal (commonly aluminum) that generally contains self-organized directional porosity; all porous anodic films are terminated by a form of barrier anodic film adjacent to the base metal surface.

**Plasma electrolytic oxidation** A process for anodizing that uses relatively high voltages that deliberately induce dielectric breakdown,

with associated sparking, on the treated component; also called micro-arc oxidation.

**Valve metal** An element from the group: aluminum, titanium, zirconium, hafnium, tungsten, niobium and tantalum. Such elements will develop protective oxide films when polarized anodically in a suitable electrolyte.

### Symbols

**MAO** Micro-arc oxidation

### 4.03.1 Practice of Anodizing

Anodic oxidation or anodizing, as applied to metallic surfaces, is the production of a coating, generally of oxide, on the surface by electrolytic treatment in a suitable solution, the metal being the anode. Although a number of metals,<sup>1</sup> including aluminum, magnesium, tantalum, titanium, vanadium and zirconium, can form such anodic films, only aluminum and its alloys, and to a lesser extent magnesium, are anodized on a significant commercial scale for corrosion protection.

The anodic oxidation of magnesium does not normally produce a film that has sufficient corrosion resistance to withstand exposure without further protection by painting, and the solutions used are complex mixtures containing phosphates, fluorides and chromates. In the case of aluminum, a relatively simple treatment produces a hard, compact, strongly adherent film of oxide, which affords considerably increased protection against corrosive attack.<sup>2,3</sup>

A further advantage of this process lies in the decorative possibilities of the oxide film, which may be almost completely transparent on very high purity aluminum (99.99% Al) and certain alloys based on this purity, and thus protects the surface without obscuring its polish or texture. On metal of lower purity, and other alloys, the oxide layer may become slightly milky, or colored grey or yellowish, although the deterioration is hardly apparent with purities down to 99.7–99.8% Al. The appearance and character of the film may also be influenced by the type of anodizing treatment, and the oxide film may be dyed to produce a wide range of colored finishes. Anodizing characteristics of a number of aluminum alloys are listed by Wernick and Pinner.<sup>3</sup> The anodizing procedures in general use are shown in Table 1, sulfuric acid being the most commonly used electrolyte. Treatment time is 15 min to 1 h.

The articles to be anodized should be free from crevices where the acid electrolyte can be trapped. They may be given a variety of mechanical and chemical pretreatments, including polishing, satin-finishing, etching, etc. but before anodizing, the surface must be clean and free from grease and polishing compound.

After the anodic treatment, the work is removed from the tank and carefully swilled with cold water to remove all traces of acid. At this stage, the anodic film is absorptive, and care should be taken to avoid contamination with oil or grease, particularly if the work is to be dyed. Dyeing may be carried out by immersion for about 20 min in an aqueous solution of the dyestuff at a temperature of 50–60 °C. Inorganic pigments may also be incorporated in the oxide layer by a process involving double decomposition. Finally, both dyed and undyed work are sealed by treatment in boiling water (distilled or deionized) or steam, which enhances the corrosion resistance and prevents further staining or leaching of dye. Solutions of metal salts, for example nickel or cobalt acetates, are often used to seal work after dyeing. Traditionally sealing in 5–10% dichromate solution, which gives the coating a yellow color, was used to impart the highest degree of corrosion resistance. However, the use of chromates is being increasingly phased out due to environmental concerns.<sup>4</sup>

In the architectural field, use is being made of integral color anodizing which is capable of producing self-colored films in a number of fade-resistant tints ranging from gray, through bronze and brown, to a warm black. The electrolytes are developments of the oxalic acid solution and consist of various dibasic organic acids, such as oxalic, malonic or maleic, or sulfonated organic acids such as sulfosalicylic acid, together with a small proportion of sulfuric acid. For constant and reproducible results, a close analytical control of the electrolyte must be maintained, particularly with respect to aluminum which dissolves as

**Table 1** Traditional anodizing processes for aluminum (the chromic acid treatment is historic and is being increasingly phased out)

<i>Electrolyte</i>	<i>Temperature (°C)</i>	<i>Applied voltage (V)</i>	<i>Current density (A m<sup>-2</sup>)</i>	<i>Film thickness (μm)</i>	<i>Appearance</i>
5–10% sulfuric acid	17–22	12–24	110–160	3–25	Transparent: colorless to milky
3–10% chromic acid	30–45	30–45	30–35	2–8	Opaque: light to dark gray
2–5% oxalic acid	20–35	30–60	110–215	10–60	Transparent: light yellow to brown

treatment proceeds, and ion-exchange resins are frequently used to regenerate the relatively expensive electrolyte and keep the aluminum in solution between controlled limits. Some typical color anodizing treatments are summarized in **Table 2**.

Alloys are generally of the Al–Mg–Si type with additions of copper and chromium or manganese. Color varies with the particular alloy and the film thickness. For optimum control of color, the alloy must be carefully produced with strict attention to composition, homogenization and heat-treatment, where appropriate, and the anodizing conditions must be maintained within narrow limits. It is usual to arrange matters, preferably with automatic control, such that current density is held constant with rising voltage up to a selected maximum, after which voltage is held steady; the whole cycle being for a fixed time. Refrigeration of the electrolyte may be necessary to maintain the temperature at the working level, owing to the relatively high wattage dissipation.

Hard anodic films, 50–100  $\mu\text{m}$  thick, for resistance to abrasion and wear under conditions of slow-speed sliding, can be produced in sulfuric acid electrolytes at high current density and low temperature.<sup>5–7</sup> Current densities range from 250 to 1000  $\text{A m}^{-2}$ , with or without superposed alternating current in 20–100  $\text{g l}^{-1}$  sulfuric acid at  $-4$  to  $10^\circ\text{C}$ . Under these conditions, special attention must be paid to the contact points to the article under treatment, in order to avoid local overheating.

The films are generally dark in color and often show a fine network of cracks due to differential expansion of oxide and metal on warming to ambient temperature. They are generally left unsealed, since sealing markedly reduces abrasion resistance, but may be impregnated with silicone oils<sup>8</sup> to improve the frictional properties. Applications include movable instrument parts, pump bodies and plungers, etc. Decorative self-colored films<sup>9</sup> can also be produced in sulfuric acid under conditions intermediate between normal and hard anodizing.

Continuously anodized sheet, foil and wire, which may be given a dyed finish, are produced through a series of cleaning, etching and anodizing tanks, with a film thickness up to about 6  $\mu\text{m}$ . Uses include electrical windings for transformers and motors, where the light weight of aluminum and the insulating and heat-resistant properties of the film are of value, and production of small or light-section articles by stamping or roll-forming.

#### 4.03.2 Mechanism of Formation of Porous Oxide Coatings

It has been established that in the case of electrolytes, such as boric acid or ammonium phosphate solutions, in which aluminum oxide is insoluble, this anodic passivity is due to the formation of a thin compact layer of aluminum oxide whose thickness is proportional to the applied voltage. In neutral phosphate solutions, for example, film growth practically ceases when the thickness corresponds to about  $1.4 \text{ nm V}^{-1}$ , and a similar value has been found for many other electrolytes of this type. These thin films have a high electrical resistance, and can withstand several hundred volts under favorable conditions.

In electrolytes in which the film has a moderate solubility, film growth is possible at lower voltages, for example, in the range 12–60 V, since the rate of formation of the oxide exceeds its rate of solution and current flow continues owing to the different structure of the oxide layer. Electron microscopy has revealed the characteristic porous structure of these films.<sup>10</sup> The pore diameter appears to be a function of the nature and concentration of the electrolyte and of its temperature, being greatest in a solution of high solvent activity, while the number of pores per unit area varies inversely with the formation voltage. In any given electrolyte, the lower the temperature and concentration, and the higher the voltage, the denser will be the coating, as the number of pores per unit

**Table 2** Traditional integral color anodizing processes

<i>Electrolyte</i>	<i>Temperature (<math>^\circ\text{C}</math>)</i>	<i>Current density (<math>\text{A m}^{-2}</math>)</i>	<i>Voltage (V)</i>	<i>Time (min)</i>
Sulfosalicylic acid ( $100 \text{ g l}^{-1}$ ) + sulfuric acid ( $50 \text{ g l}^{-1}$ )	22–25	215–320	25–70	20–45
4- or 5-Sulfophthalic acid ( $75\text{--}100 \text{ g l}^{-1}$ ) + sulfuric acid ( $8\text{--}10 \text{ g l}^{-1}$ )	15–30	130–370	>70	30
Oxalic acid ( $80 \text{ g l}^{-1}$ to saturation)	15–25	130–160	35–70	50–90

area are reduced under these conditions; Table 3 illustrates these points.

In order to account for the relatively high potential required to maintain the current it was suggested by Setoh and Miyata<sup>11</sup> that a thin barrier-layer, similar to that formed in nonsolvent electrolytes, is present below the porous layer. This view has been supported by later work involving capacity and voltage-current measurements, which have allowed the thickness of the barrier-layer to be computed.<sup>12</sup> As in the case of electrolytes which produce barrier films, the thickness has been found to be proportional to the anodizing voltage, but is lower than the limiting growth rate of  $1 \text{ nm V}^{-1}$  and varies with the anodizing conditions (Table 4). The morphology of the anodic film is shown in Figure 1 and diagrammatically in Figure 2.

The more or less regular pattern of pores imposes a cellular structure on the film, with the cells approximating in plan to hexagons, each with a central pore.<sup>13-15</sup> A barrier layer separates the pores from the aluminum, the alumina cells can self-organize to a close-packed arrangement,<sup>13,16</sup> with groups of cells having a potential for organization into regular patterns.<sup>13,16-18</sup> The pore diameter and barrier layer thickness are related to the anodizing voltage, with

ratios of about  $1.0 \text{ nm V}^{-1}$ , with an increased ratio of about  $2.8 \text{ nm V}^{-1}$  for the cell width.<sup>19</sup> The metal surface underlying the film, therefore, consists of a close-packed regular array of nearly hemispherical depressions which increase in size with the anodizing voltage. The thickness of the individual cell walls is approximately equal to that of the barrier-layer.<sup>20</sup>

In view of its position in the electrochemical series ( $E^0 \text{ Al}^{3+}/\text{Al} = -1.66 \text{ V (SHE)}$ ), aluminum would be expected to be rapidly attacked even by dilute solutions of relatively weak acids. In fact, the rate of chemical attack is slow, owing to the presence on the aluminum of a thin compact film of air-formed oxide. When a voltage is applied to an aluminum anode there is a sudden initial surge of current, followed by a rapid fall to a lower, fairly steady value. It appears that this is due to the formation of a barrier-layer. Before the limiting thickness is reached; however, the solvent action of the electrolyte initiates a system of pores at weak points or discontinuities in the oxide barrier-layer.

Pore initiation may be associated with irregularities in original air-formed film on the metal. The development of locally thicker film regions with subsequent pore initiation in the thinner film region is related to the substrate texture. Initial uniform film thickening is apparent, followed by development of locally thicker film material above the distinct metal ridges upon the aluminum surface after pretreatment, and eventual pore development in preferred regions of thinner film between the protuberances, as shown in Figure 3.<sup>21-23</sup>

Growth of oxide continues on a series of hemispherical fronts centered on the pore bases, provided that the effective barrier-layer thickness between the metal surface and the electrolyte within the pores, represented by the hemisphere radius, is approximately  $1 \text{ nm V}^{-1}$ . As anodic oxidation proceeds at a uniform rate, a close-packed hexagonal cell-pattern is produced, the inward extension of the pore due to solution of oxide keeping pace with the inward movement of the oxide-metal interface, as shown by the arrows in Figure 2.

Radiochemical and electron microscopy studies<sup>21-25</sup> indicate that the pore base is the actual site of formation of aluminum oxide. The high electric field that exists across the barrier layer drives the transport of  $\text{Al}^{3+}$  and  $\text{O}^{2-}$  ions through the barrier layer, which is necessary for film growth.<sup>23,26</sup> The formation of porosity has mainly been attributed to field-accelerated dissolution of anodic alumina at the base of each pore,<sup>22,23</sup> which is also enhanced by the heating

**Table 3** Number of pores in anodic oxide coatings

Electrolyte	Temperature (°C)	Applied voltage (V)	Pores ( $\text{cm}^{-2}$ )
15% sulfuric acid	10	15	$77 \times 10^9$
	10	20	$51 \times 10^9$
	10	30	$28 \times 10^9$
3% chromic acid	49	20	$22 \times 10^9$
	49	40	$8 \times 10^9$
	49	60	$4 \times 10^9$
2% oxalic acid	24	20	$36 \times 10^9$
	24	40	$12 \times 10^9$
	24	60	$6 \times 10^9$

**Figure 2** Diagrammatic cross-section of porous anodic oxide film.

effect of the current, but will also be limited by diffusion. In a process that is separate to field-assisted dissolution, the  $\text{Al}^{3+}$  ions that migrate to the pore base are ejected directly to the electrolyte,<sup>23</sup> that is, without formation of anodic alumina, such that new film is formed due to the inward migration of  $\text{O}^{2-}$  ions. It has been shown that the freshly formed oxide,  $\alpha\text{-Al}_2\text{O}_3$ , is amorphous.<sup>27</sup> The very early stages of pore growth have been extensively studied, and the importance of surface topography and flaw sites in the preexisting oxide established by O'Sullivan, Wood<sup>24</sup> and Thompson and Wood<sup>28</sup> using electron microscopy. Prolonged action of the acid electrolyte on thick films may cause the pores to become conical in section, widening towards the upper surface of the film. This will impose an upper limit on film thickness in solvent electrolytes, as found in practice.

For color anodizing, although it might seem at first sight that dyestuffs are merely held mechanically within the pores, and this view is probably correct in the case of inorganic pigments, there is some support for the opinion that only those dyestuffs which form aluminum–metal complexes produce really light-fast colorations. The effect of hot water sealing is to convert anhydrous  $\gamma\text{-Al}_2\text{O}_3$  into the crystalline monohydrate,  $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ , which occupies a greater volume and blocks up the pores, thus preventing further absorption of dyes or contaminants. The monohydrate is also less reactive.

### 4.03.3 Properties of Coatings

#### 4.03.3.1 Composition

The main constituent of the film is aluminum oxide, in a form which varies in constitution between amorphous  $\text{Al}_2\text{O}_3$  and  $\gamma\text{-Al}_2\text{O}_3$ , together with some monohydrate,  $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ . In the presence of moisture, both the anhydrous forms are gradually transformed into the monohydrate, and the water content of as-formed films is, therefore, somewhat variable.

After sealing in boiling water, the composition of the completely hydrated film obtained when using sulfuric acid approximates to: 70%  $\text{Al}_2\text{O}_3$ , 17%  $\text{H}_2\text{O}$ , 13%  $\text{SO}_3$ . It is probable that the  $\text{SO}_3$  is combined with the aluminum as a basic sulfate. Sealed films show the electron diffraction pattern of the monohydrate, beohmite.

Anion incorporation in the film is a further important factor affecting film characteristics. It has been

**Figure 3** Transmission electron micrographs of ultramicrotomed cross-section of porous anodic film in the early stages of development. The arrow in (b) highlights a local crack/repair event.

found that anion species are incorporated into the films produced in the main acids, including oxalic acid, sulfuric acid, phosphoric acid and boric acid-formamide electrolytes.<sup>29</sup> The levels of acid anion incorporation are generally in the order: sulfuric acid > phosphoric acid > oxalic acid > chromic acid. Using a radiotracer technique and electron probe microanalysis, sulfur incorporation in films formed in sulfuric acid were determined. A typical level of 4–18 wt% sulfur was found, distributed uniformly throughout film thickness, by different researchers.<sup>30–33</sup> Anodizing in chromic acid produces contrasting results from films formed in sulfuric, oxalic, phosphoric acids; the films contain relatively low levels of chromate incorporation.

The distribution of the anion present after anodizing in oxalic acid has been studied by Rutherford back scattering (RBS) and Auger electron spectroscopy (AES).<sup>34</sup> Carbon is present in the oxide layer in measurable concentrations. The carbon concentration shows a maximum at the surface, a slow decrease through the oxide, and with no signal within a thin oxide region adjacent to the metal. An oxalate content of about 2.4 wt% in films formed in oxalic acid was reported.<sup>35</sup>

#### 4.03.3.2 Density

Owing to the variable degree of porosity of the anodic film, it is only possible to determine the apparent density, which varies with the anodizing conditions and also with the film thickness. **Figure 4** shows the variation in density with thickness for steam-sealed anodic films produced in sulfuric acid on aluminum of 99.99% and 99.5% purity. A mean figure of  $2.7 \text{ g cm}^{-3}$  for sealed, and  $2.5 \text{ g cm}^{-3}$  for unsealed films is accepted by the British Standard for anodized aluminum.<sup>36</sup>

#### 4.03.3.3 Mechanical Properties

##### 4.03.3.3.1 Hardness

It is not possible to obtain a reliable figure for the hardness of anodic coatings with either the indentation or scratch methods, because of the influence of the relatively soft metal beneath the anodic film, and the presence of a soft outer layer on thick films. On Moh's scale, the hardness of normal anodic films lies between 7 and 8, that is, between quartz and topaz.

Methods are available for the determination of relative abrasion resistance using either a mixed jet

**Figure 4** Apparent density of anodic film as a function of film thickness. Reproduced from *Aluminium, Berl.* **1938**, 32, 126.

of air and abrasive, as recommended in the appropriate British Standard<sup>37</sup> or an abrasive wheel or disc. Owing to variations in the quality of the abrasive, and the performance of individual jets, a standard comparison sample is included in each batch.

The hardness of the film is markedly affected by the conditions of anodizing. By means of special methods involving dilute electrolytes at low temperatures and relatively high voltages, with or without superimposed alternating current, it is possible to produce compact abrasion-resistant films with thicknesses of 50–75 μm and hardness of 200–500 Vickers, for special applications.

#### 4.03.3.3.2 Flexibility

The normal anodic film begins to crack if subjected to an extension exceeding about 0.5%. Thinner films up to 5 μm in thickness appear to withstand a greater degree of deformation without obvious failure, and are often used for dyed coatings on continuously anodized strip from which small items may be punched or stamped. Continuously anodized wire can be bent round a radius of 10–15 times its diameter without visible crazing. A greater degree of flexibility is also shown by the more porous coatings produced in 20–25% sulfuric acid at 35–40 °C, while hard films are much less flexible. Unsealed films are only slightly more flexible than films sealed in water or dichromate solution.

#### 4.03.3.4 Electrical Properties

The specific resistance of the dry anodic film is  $4 \times 10^{15} \Omega \text{ cm}$  at 20 °C,<sup>38</sup> while the dielectric constant of anodic oxide films has been found to be 5.0–5.9 for sulfuric films, and 7–8 for oxalic films. A mean value of 7.45 has been quoted for barrier-layer films,<sup>1</sup> but more recent work favors a value closer to 8.7.<sup>39</sup>

The breakdown voltage of an anodic film varies with the method of measurement and conditions of anodizing, and shows fluctuations over the surface. In the case of unsealed films, breakdown voltage also depends on the relative humidity at the time of measurement. It is normally measured by applying a slowly increasing alternating voltage between a loaded hemispherical probe on the upper surface of the film, and the underlying metal, contact to which may be established by removing a portion of the film. The breakdown voltage–thickness relationship for sealed films up to about 20 μm is approximately linear, and the slope of the curve for sulfuric acid films varies from 30 to 40 V μm<sup>-1</sup>. These results were obtained with a relatively high loading on the probe; with reduced load (approx. 60 g and below on a hemispherical probe of 1.6 mm radius) values of 60–100 V μm<sup>-1</sup> can be reached. The higher figures probably represent limiting values which will apply to the conditions between adjacent laps or turns on coils wound from anodized strip or wire.

#### 4.03.3.5 Physical Properties

The thermal expansion of the film is only about one-fifth that of aluminum,<sup>1</sup> and cracking or crazing is observed when anodized aluminum is heated above 80 °C. The fine hair-cracks produced do not seem to impair the protective properties of the coating if anodizing conditions have been correct.

The thermal conductivity of anodized films is approximately one-tenth that of aluminum.<sup>2</sup> Also, apart from hair-cracks, little change is observable in the anodic film on heating up to 300–350 °C, although some dyed finishes may change color at 200–250 °C, but at higher temperatures up to the melting point of

the metal, films may become opaque or change color, owing to loss of combined water, without losing their adhesion.

#### 4.03.3.6 Thermal Properties

**Table 5** shows the total heat emissivity of various aluminum surfaces, as a percentage of that of a black body. The emissivity of anodized aluminum rises rapidly with film thickness up to 3  $\mu\text{m}$  after which the rate of increase diminishes.

The heat reflectivity of as-rolled aluminum is about 95%, but this high value may not be maintained for long in a corrosive atmosphere, although it is less affected by surface finish than is optical reflectivity. Anodizing reduces the heat reflectivity, owing to absorption by the oxide layer; this effect increases with film thickness. There is a deep absorption trough in the region corresponding to a wavelength of 3  $\mu\text{m}$ ; this is probably due to the  $-\text{OH}$  grouping in the hydrate, the effects of which may be minimized

**Table 5** Relative heat emissivity of various aluminum surfaces

Surface	Heat emissivity (%)
Highly polished	4.3–6.4
Etched	6.4–8.5
Bright roll finish	5.3–7.4
Malt roll finish	8.5–16
Aluminum paint	17–32
Diecast	16–26
Sandcast	26–36
Anodized, according to film thickness	38–92
Black body	100

Data recalculated from Hase, R. *Aluminium*, Berl. **1942**, 24, 140.

by sealing the heated film in oil instead of water.<sup>40</sup> This treatment is particularly valuable for heat reflectors in apparatus using sources running at 900–1000 °C, which show a peak emission in the 2–3  $\mu\text{m}$  region. **Figure 5** shows the heat reflectivity of anodized superpurity aluminum for a source of this type plotted against film thickness. The benefits of the modified sealing treatment are obvious.

#### 4.03.3.7 Optical Properties

The refractive index of the clear anodic film produced on aluminum of the highest purity in sulfuric acid is 1.59 in the as-formed condition, rising to 1.62 after sealing.<sup>41</sup> The total and specular reflectivities of an anodized aluminum surface are controlled by both the condition of the metal surface, polished or matt, and the absorption or light-scattering properties of the oxide layer. Total reflectivity may be defined as the percentage of the incident light reflected at all angles, while specular reflectivity is that percentage reflected within a relatively narrow cone with its axis along the angle of reflection. For many years, the standard instrument for measuring specular reflectivity has been that designed by Guild,<sup>42</sup> but more recently a modified gloss head giving rather greater discrimination has been described by Scott.<sup>43</sup> Other instruments, while placing a number of surfaces of varying specularly in the same relative order, may give different values for the specular reflectivity.

The general brightness of a surface is chiefly dependent upon the total reflectivity  $T$ , while specular reflectivity  $S$  controls the character of the reflected image. In assessing the subjective brightness of a surface the eye tends to be influenced more by

**Figure 5** Heat reflectivity of anodized aluminum. Reproduced from Pearson, T. G.; Phillips, H. W. L. *Metallurg. Rev.* **1957**, 2(8), 348.

the  $S/T$  ratio or image clarity than by the total reflectivity.

For a high degree of specularity, the metal surface must be given a high polish by mechanical means; this may be followed (or replaced) by electrochemical or chemical brightening. When such a brightened surface is protected by anodizing, however, insoluble impurities (mainly iron and silicon) present in the aluminum will be incorporated in the anodic film and will increase its tendency to absorb or scatter light. Only metal of the highest purity, 99.99% Al, produces a fully transparent oxide film, while lower purities show decreased total reflectivities and the fraction of specular reflectivity ( $S$ ) as a function of total reflectivity ( $T$ ), the  $S/T$  ratio, after anodizing because of the increased opacity of the anodic film. **Table 6** demonstrates these effects. The figures were obtained using the Guild meter on electrobrightened and anodized metal.

#### 4.03.3.8 Effect of Anodizing on Mechanical Properties

The tensile strength of thin sections of aluminum may be somewhat reduced by anodizing, owing to the brittleness of the coating and the reduction in metallic cross-section, but this effect is normally very slight. Thin sheet, less than about 0.6 mm with a relatively thick anodic coating, also has a tendency to break more easily on bending. The incompressibility of the anodic film on the inside of the bend

probably enhances this effect, which is also seen on anodized wire.

Anodizing should be used with caution on components likely to encounter high stresses, owing to the deterioration in fatigue properties liable to result under these conditions, but under light loading and with the thinner coatings, the reduction is negligible. In some cases,<sup>44</sup> an actual improvement has been reported. The coefficient of friction of the sealed anodic film is 0.76, falling to 0.19 after impregnation with silicone oil.<sup>45</sup> These results were obtained with anodized wire.

#### 4.03.3.9 Measurement of Film Thickness

The thickness of an anodic film may be determined by a variety of nondestructive methods. Some of these are capable of a high degree of precision, while simpler methods are available for rough sorting. A number of instruments employing the eddy-current principle, with which, after prior calibration, a rapid estimate of film thickness may be made, are now available. With the best instruments, an accuracy of  $\pm 1 \mu\text{m}$  can be obtained. For approximate determinations of thickness, the breakdown voltage of the film may be measured. Breakdown voltage shows wide variations with anodizing conditions and metal or alloy composition. A separate calibration curve is, therefore, needed for each treatment. Accuracy is comparatively low, rarely being greater than  $\pm 2\%$  of the total film thickness.

Alternatively, the loss in weight<sup>46</sup> of an anodized sample of known area may be found after the film has been stripped in a boiling solution made up with phosphoric acid (specific gravity 1.75) 3.5 vol.% and chromic acid 2.0 wt%. Immersion for 10 min is usually sufficient to remove the film without the metal being attacked. Further, film thickness can be precisely determined by cross-sectional examination in a scanning electron microscope or a transmission electron microscope.

#### 4.03.4 Corrosion Resistance

Since the natural passivity of aluminum is due to the thin film of oxide formed by the action of the atmosphere, it is not unexpected that the thicker films formed by anodic oxidation afford considerable protection against corrosive influences, provided the oxide layer is continuous, and free from macropores. The protective action of the film is considerably enhanced by effective sealing, which plugs the mouths of the micropores formed in the normal course of anodizing with hydrated oxide, and still

**Table 6** Effect of metal purity and anodic film thickness on reflectivity

Metal purity (%)	Film thickness ( $\mu\text{m}$ )					
	2		5		10	
	$T$	$S/T$	$T$	$S/T$	$T$	$S/T$
99.5	80	0.84	79	0.83	77	0.78
99.8	82	0.95	83	0.95	—	—
99.99 (super purity)	84	0.99	84	0.99	84	0.99
Super purity + 0.5 Mg	84	0.98	84	0.98	83	0.97
Super purity + 1.25 Mg	83	0.99	83	0.99	82	0.99
Super purity + 0.7 Mg, 0.3 Si, 0.25 Cu	82	0.99	79	0.98	—	—

$S$ , Specular reflectivity;  $T$ , Total reflectivity.

Data reproduced from Pearson, T. G.; Phillips, H. W. L. *Metallurg. Rev.* **1957**, 2(8), 348.

further improvement may be afforded by the incorporation of corrosion inhibitors, such as dichromates, in the sealing solution. Chromic acid films, in spite of their thinness, show good corrosion resistance.

The protective action of sulfuric films is mainly controlled by the anodizing conditions, compact films formed at temperatures below 20 °C in 7% (v/v) sulfuric acid being more resistant than the films formed at higher temperatures in more concentrated acid. The wider pores of the latter result in less protection but these films are more readily dyed. Greater protection is also given by thicker films, and a thickness of about 25 µm is generally considered adequate for architectural work in a normal urban environment. In a heavily polluted industrial area, even thicker films may be desirable, while in rural areas some reduction would be permissible. Bright anodized motorcar trim is generally given a film thickness of about 7 µm.

Alumina monohydrate in the mass is very unreactive, being rapidly attacked only by hot sulfuric acid or caustic soda solutions, and the anodic coating shows similar characteristics to some degree. The presence in the film of macropores due to localized impurities, intermetallic particles or contaminations in the metal and overlying oxide can bring about rapid penetration, owing to the concentration of attack at the few vulnerable points. Metal of good quality specially produced for anodizing should therefore be used in order to ensure that such weak points are absent. For vessels and tanks for holding liquids, it may be preferable to use unanodized aluminum, and to accept generalized corrosive attack rather than run the risk of perforation, which may occur with anodized metal.

For ordinary atmospheric exposure, it is usually possible to arrange that thin spots of the film, such as the contact points of the anodizing jigs, are located in relatively unimportant positions on the article and are hidden from view.

Since the corrosion resistance of anodic films on aluminum is markedly dependent on the efficacy of sealing (provided the film thickness is adequate for the service conditions), tests for sealing quality are frequently employed as an index of potential resistance to corrosion. While it is admitted that an unequivocal evaluation of corrosion behavior can only be obtained by protracted field tests in service, accelerated corrosion tests under closely controlled conditions can also provide useful information in a shorter time within the limitations of the particular test environment employed.

Tests for sealing include dye staining tests such as that specified in BS EN 12373-4:1999, involving preliminary attack with acid, followed by treatment with dye solution. Nitric acid<sup>47,48</sup> or a sulfuric acid/fluoride mixture may be used for the initial attack, and a rapid spot test<sup>49</sup> has been developed using the acid/fluoride mixture, followed by a solution of 10 g l<sup>-1</sup> Aluminum Fast Red B3LW. Poor sealing is revealed by a deep pink to red spot, while good sealing gives nearly colorless to pale pink colorations. The test can be applied to architectural or other material on site.

Physical tests of film impedance<sup>50</sup> using an a.c. bridge have also been recommended, although the correlation with corrosion resistance is necessarily empirical. Film impedance increases at an approximately linear rate with sealing time and film thickness.

Exposure of the samples to a controlled moist atmosphere containing sulfur dioxide, as recommended in ISO 12473:2006, is an example of a test bridging the gap between sealing tests and accelerated corrosion tests. After exposure for 24 h at 25 ± 2 °C, poorly sealed films show a persistent heavy white bloom, while good sealing produces at the most a slight superficial bloom.

A rapid immersion test in a hot aqueous solution containing sulfur dioxide has also been developed by Kape<sup>44</sup> and is specified in ISO 12473:2006. Results are similar to those obtained in the preceding test, Method H. The method can also be made quantitative by measuring the weight loss.

The accelerated corrosion test in most general use is the copper accelerated acetic acid (CASS) test<sup>51</sup> in which the articles are sprayed intermittently with a solution made up with 5% NaCl, 0.026% CuCl<sub>2</sub>·H<sub>2</sub>O acidified to pH 2.8–3.0 with acetic acid. The specimens are clamped at an angle of 15° to the vertical in a baffled enclosure maintained at 50 °C, and the exposure time is 24–96 h. Corrosive attack of inadequately sealed or thin films is shown by pitting.

A derivative of the CASS test is known as the Ford Anodized Aluminium Corrosion Test (FACT).<sup>52</sup> This makes use of a controlled electrolytic attack using the CASS solution. The electrolyte is contained in a glass test cell and clamped against the anodized surface with a Neoprene sealing gasket. A d.c. voltage of 200 V in series with a high resistance is maintained between an anode of platinum wire and the aluminum test piece as cathode. The integrated fall in potential across the cell over a fixed period of 3 min as corrosion proceeds and an increasing current flows, is taken as a measure of the corrosion resistance. Remarkably good correlation has been obtained between

the readings of this instrument and the amount of pitting after exposure at a number of outdoor sites.<sup>53,54</sup> Comprehensive reviews of sealing techniques including test methods and corrosion behavior have been published by Thomas<sup>55</sup> and Wood.<sup>56</sup>

The behavior of samples under the actual conditions of service is the final criterion, but unfortunately such observations take a long time to collect and assess, and the cautious extrapolation of data from accelerated tests must be relied on for forecasting the behavior of anodized aluminum in any new environment.

#### 4.03.4.1 Atmospheric Exposure

Table 7 shows the effects of thin anodic oxide films on the resistance to industrial and synthetic marine atmospheres (intermittent salt spray) of three grades of pure aluminum. The results show how relatively thin films produce a marked improvement in both environments.

In an industrial atmosphere, an anodic film only 6.5  $\mu\text{m}$  thick provides a twofold increase in life over unprotected metal, and the effect under salt-spray conditions is even greater. It is interesting to note that both the industrial atmosphere and salt-spray results show parallel trends. A similar improvement in expectation of life for thin anodic coatings has been reported by Phillips<sup>57</sup> for 99.5% Al, and for alloys of the following compositions: Al–1.25Mn; Al–2Mg–1Mn; Al–1Mg–1Si. The results for a high-copper alloy were less good.

An interesting paper by Lattey and Neunzig<sup>58</sup> shows that the better the surface finish of the aluminum

the thinner the coating required for protection. Neunzig<sup>59</sup> has also studied the effect of the hair-cracks produced by heating or bending on corrosion resistance. Although pitting was initiated by such cracks in thin films (5  $\mu\text{m}$ ), serious pitting in thicker films (15  $\mu\text{m}$ ) was observed only if anodizing had been carried out at 25 °C; films produced at 16–17 °C were more resistant to corrosive attack. This reemphasizes the importance of maintaining correct anodizing conditions for maximum corrosion resistance.

Results of exposure tests for 10 years in a severe industrial environment at Stratford, London, have been reported by the Fulmer Research Institute.<sup>60</sup> A range of pure and alloy specimens, anodized to a maximum film thickness of about 25  $\mu\text{m}$ , was exposed at an angle of 45°. Corrosion was assessed visually, by determination of weight loss after cleaning, and by reflectivity measurements. All specimens showed signs of pitting, and there was a considerable loss of reflectivity, the under surface being more affected than the upper. A striking feature of the results was the accelerating rate of deterioration in the final five years of exposure. Although none of the samples was completely protected, results were better for the purer specimens and the thicker films.

#### 4.03.4.2 Maintenance

In architectural work, particular care must be taken to avoid destructive attack of the anodic film by alkaline mortar or cement during erection, and temporary coatings of spirit-soluble waxes, or acetate–butyrate lacquers are frequently applied to window frames and the like to protect against mortar splashes,

**Table 7** Corrosion tests on unprotected and anodized pure aluminum

Corrosive effect		Grade 1B (99.5%)			Grade 1A (99.8%)		Super purity (99.99%)	
		Film thickness ( $\mu\text{m}$ )			Film thickness ( $\mu\text{m}$ )		Film thickness ( $\mu\text{m}$ )	
		0	6.5	0	4	6.5	0	4
Industrial atmosphere (7 years exposure)	Appearance <sup>a</sup> (life in years)	2.5	5	2.5	.5	5	3.5	6
	Mechanical properties (life in years)	2.75	5.5	3	4.5	6	3	5

which in any event should be removed at the earliest possible moment.

The resistance of properly anodized aluminum exposed to the weather can be considerably enhanced by correct and regular cleaning. Deposits of soot and dirt should be removed by washing with warm water containing a nonaggressive detergent; abrasives should not be used. For window frames this washing may conveniently be carried out when the glass is cleaned in the normal way. In such circumstances the life of the coating may be prolonged almost indefinitely, as exemplified by the good condition of the chromic-anodized window frames of Cambridge University Library which were installed in 1933, and of the sulfuric-anodized window frames of the New Bodleian Library, Oxford University, installed in 1938.

### 4.03.5 Recent Developments

#### 4.03.5.1 Practice of Anodizing

Although there have been few changes in the basic anodizing practices, and sulfuric acid is the electrolyte used in most plants, there have been many developments in the pretreatment, coloring and sealing processes associated with anodizing.

The increasingly stricter regulations on the toxicological and environmental issues associated with hexavalent chromium have pushed research efforts focused on the replacement of chromic acid anodizing.<sup>61–65</sup> Different weak organic acid additions, such as boric acid<sup>66</sup> or tartaric acid<sup>67</sup> to sulfuric acid anodizing baths have been proposed. Tartaric/sulfuric acid anodizing (TSA) has proven to produce porous anodic film comparable to those formed in chromic acid baths.

Over recent years, new anodizing processes have been developed. These processes do not utilize hexavalent chromium species and hydrofluoric acid and as such have environmental advantages over some earlier processes. For instance, research on plasma electrolytic oxidation (PEO),<sup>68–78</sup> also known as microarc oxidation (MAO), has been revived since the late 1980s. PEO is an electrochemical surface treatment process for generating oxide coatings on metals. It is an anodizing processes with the use of relatively high voltages that lead to dielectric breakdown, with sparking, on the treated component. During the process, discharges occur and the resulting plasma modifies (and enhances) the structure of the oxide layer. This process can be used to grow thick (tens or hundreds of micrometers), largely crystalline, oxide coatings on metals such as aluminum,

magnesium and titanium. The resultant coatings can offer protection against wear, corrosion or heat as well as electrical insulation due to their high hardness and a continuous barrier layer.

The trend in architectural applications has been towards more matt finishes, and the sodium hydroxide-based etchants used frequently contain additives such as sodium nitrate or nitrite or sodium fluoride. Chelating agents such as gluconates, heptonates or sorbitol are added to complex the aluminum produced, and other additives such as sulfides may be present in the etchant to complex zinc dissolved from the alloy, and allow it to be used continuously without dumping.<sup>79</sup>

In terms of anodizing itself, the introduction of a standard for architectural applications of anodized aluminum,<sup>80</sup> and the European development of the Qualanod quality labeling scheme for architectural anodizing,<sup>81,82</sup> have been significant factors in the general improvement in the standard of anodizing. Both of these standards require the use of thick coatings (20 or 25  $\mu\text{m}$ ), which are sealed to a high quality level. The production of such coatings requires good control of operating parameters, particularly the anodizing electrolyte temperature, which should be below 21 °C.<sup>83</sup>

The field of color anodizing has changed considerably since the late 1960s. At that time the integral color anodizing processes were dominant in architectural applications, and electrolytic coloring was relatively new. Now, mainly because of the high energy costs associated with integral color processes, electrolytic coloring is by far the most widely used technique.

In order to produce color by this method, the anodized work is rinsed and transferred to a suitable metal salt solution. The process is electrolytic, and a.c. is passed between the work and a metal or graphite counter-electrode, causing the metal present in the solution to be deposited at the base of the pores of the anodic coating.<sup>84</sup> The height of the metal deposited in the pores controls the depth of color, and a range of shades is produced by varying the applied voltage and time. Ranges of bronze and black finishes are produced in nickel-, cobalt-, or tin-based electrolytes, and pink, maroon, or black finishes in electrolytes based on copper. The electrolytes usually contain the appropriate metal sulfate, with many other additives present to adjust or control pH, to improve throwing power, or to make dark colors easier to produce. Nickel and cobalt electrolytes are used at pH values of 4–6, and tin and copper electrolytes at pH values of 1–2; an applied voltage of the order of 10–20 V and a current density of about 30–50  $\text{A m}^{-2}$  are normally required.

The finishes produced have very good light fastness and corrosion resistance, and, unlike integral color finishes, the shade is largely independent of the aluminum alloy and the anodic film thickness used. The whole range of shades can be produced on films as thin as 5  $\mu\text{m}$ , so the finishes are also being used in trim applications.<sup>85</sup> Many patents and publications in the electrolytic coloring field now exist and they have been reviewed by many authors.<sup>86,87</sup>

In order to obtain a wider range of colored finishes, electrolytic coloring processes have been combined with conventional dyeing.<sup>88</sup> The work is anodized normally to the required film thickness, electrolytically colored in a cobalt- or tin-based electrolyte to a light bronze shade, and then over-dyed in an appropriate dyestuff to give muted shades of red, blue, yellow, or brown. Again the main application is architectural, and the finishes have good light fastness and durability. An alternative approach to widening the color range with electrolytic coloring has been the development of finishes based on optical interference effects,<sup>89</sup> whereby quite different colors can be produced in the same electrolyte. An intermediate treatment in a phosphoric acid anodizing electrolyte is normally required, between anodizing and electrolytic coloring, to produce these effects.

With the increasing use of color anodized finishes, sealing quality has become very important, and seal quality tests and standards have all improved. Sealing smut is more visible on colored than on clear anodized surfaces, and it has become common practice to try to eliminate this chemically, rather than removing it by hand wiping. Approaches to this include dipping in mineral acids after sealing,<sup>90</sup> and adding surface active agents which prevent smut forming.<sup>91,92</sup>

Sealing is normally carried out in boiling water and the high energy costs involved have led to the development of alternative, lower-energy methods. Approaches have included the use of boehmite accelerators such as triethanolamines to shorten the sealing time,<sup>93</sup> and the use of so-called 'cold' sealing systems. These latter approaches have mainly been developed in Italy,<sup>94</sup> and are based on the use of nickel salts in the presence of fluorides. They are used at a temperature of about 30 °C for a time of 15 min, and are claimed to give good corrosion resistance.

#### 4.03.5.2 Mechanism of Anodizing

The development of sophisticated electron-optical techniques now allows the direct observation of the barrier layer and the pore structure of all types of

anodic coating. Much of the most relevant work has been carried out at the University of Manchester.

For example using a tungsten tracer layer that is incorporated into the anodic film from the aluminum substrate has indicated a major role for oxide growth stresses in the origin of porosity.<sup>95–98</sup> The stresses result in flow of the relatively plastic film material in the barrier layer region of the porous film, which proceeds from beneath the pores toward the cell walls. The redistribution of film material contributes to an enhanced thickness of the film relative to that of the metal consumed. Such stress-driven pore generation is probably an important factor in the potential for self-ordering of porosity in anodic alumina.<sup>99, 100</sup> The behavior is contrary to expectations of a dissolution model of pore formation.

The morphology of porous anodic films are significantly affected by alloying elements in aluminum alloys. Thus, morphologies of porous anodic alumina films on aluminum alloys containing copper often differ greatly from that on high purity aluminum, as shown in [Figure 6](#). The well-developed cellular morphology of the classic porous film<sup>11,101,102</sup> is largely absent. In contrast, the porosity in the anodic film is irregular and can incorporate a component with a lateral alignment in cross-sections of the film.

From studies of barrier films, it was revealed that alloying elements with Gibbs free energies of oxide formation per equivalent greater than that of alumina enrich at the alloy–film interface; when a critical enrichment is reached, oxidation of the alloying elements occurs; for alloying elements with oxides of lower Gibbs free energies than that of alumina, immediate oxidation, along with aluminum, is evident from the commencement of anodizing.<sup>103–108</sup> For copper-containing alloys, copper can be significantly enriched in the alloy immediately beneath the anodic film, up to 40 at.% Cu, by the initial formation of a copper-free alumina film.<sup>109–111</sup> The enriched alloy layer is typically about 2 nm in thickness. Following enrichment, copper can be oxidized, and incorporated into the anodic film as  $\text{Cu}^{2+}$  species.<sup>112</sup> About the same time that the oxidation of copper commences, oxygen is generated within the anodic film, with associated formation of bubbles of high pressure gas.<sup>113,114</sup>

The pore morphology of the porous anodic films formed on copper-containing alloys is associated with the generation of oxygen gas bubbles and their subsequent disruption. The film disruption leads to an altered direction of pore propagation, before the pore reestablishes a normal orientation with respect

**Figure 6** Transmission electron micrographs of ultramicrotomed sections of aluminum alloys following anodizing in chromic acid (DEF STAN 03-24/2): (a) AA1050 and (b) AA2024. Reproduced from Zhou, X.; Thompson, G. E.; Skeldon, P. In Proceedings of the 17th International Corrosion Congress, Las Vegas, USA, 2008; Paper 3972.

to the local alloy–film interface. The changing directions of pores contribute to a lateral aspect of the pore morphology.<sup>101,115</sup>

The mechanism of coloring with integral color finishes has been shown to depend on the presence of free metallic aluminum in the film, as well as on the inclusion of intermetallic constituents.<sup>116</sup> With electrolytic coloring processes, color is produced by light scattering effects, with the tiny metallic deposits within individual pores acting as light scattering centers.<sup>126</sup> Distribution of metal in the pores varies from one electrolyte to another, and this can affect the corrosion resistance of the final product.<sup>127</sup>

The mechanism of sealing has been shown to involve an initial dissolution and reprecipitation of hydrated aluminum oxide on the pore walls, pseudo-boehmite gel formation within the pores, and conversion of this to crystalline boehmite at the film surface.<sup>117</sup> The presence of an intermediate layer close to the film surface, in which the identity of the original pores has been lost, has also been recognized.<sup>118</sup>

#### 4.03.5.3 Properties of Coatings

The hardness and abrasion resistance of anodic coatings have never been easy properties to measure, but the development of a British Standard on hard anodizing<sup>119</sup> has made this essential. Film hardness is best measured by making microhardness indents on a cross-section of a film,<sup>120,121</sup> but a minimum film thickness of 25 μm is required. For abrasion resistance measurements, a test based on a loaded abrasive

wheel,<sup>122</sup> which moves backwards and forwards over the film surface, has improved the sensitivity of such measurements.

#### 4.03.5.4 Test Methods

Tests for quality of sealing of anodic coatings have become internationally standardized. They include dye spot tests with prior acid treatment of the surface (ISO 2143:1981 and BS EN 12373-4:1999), measurement of admittance or impedance (ISO 2931:1983 and BS EN 12373-5:1999), or measurement of weight loss after acid immersion (ISO 3210:1983 and 12373-6:1999, BS EN 12373-7:2002). Of these the chromic-phosphoric acid immersion test (ISO 3210) has become the generally accepted reference test.

The revision of the main anodizing standard (BS 1615:1987) has changed it from a ‘specification’ to a ‘method for specifying,’ but it provides all the information necessary to write an appropriate specification for any anodized product.

### 4.04.1 Introduction

The application of metallic coatings for the protection of metals may be required for one or more of the following reasons:

- to prevent or reduce corrosion of the substrate metal;
- to modify the physical or mechanical properties of the substrate metal;

<sup>†</sup>Deceased.

- (c) to achieve and maintain some desired decorative effect.

Many coatings also have a role in wear resistance and may have other important properties to be considered, for example, silver electrodeposits for electrical contacts.

Although the initial choice of coating material applied for reasons (b) or (c) may be dictated by the particular properties required, the corrosion behavior of the composite metal coating–metal substrate system must also be taken into consideration insofar as it may affect the maintenance of the desired properties. Consequently, in all cases where protective metal coatings are used, the corrosion performance of both coating and substrate requires careful consideration.

The choice of substrate metal is usually governed by cost and weight as well as general physical, mechanical or, fabrication properties, and these factors will normally dictate a very limited number of possible materials none of which may be ideal in resisting the corrosive environment that will be encountered in service. Ideally, a protective metal coating should exclude completely the corrosive environment from the substrate metal and, if this can be achieved, only the resistance of the coating metal itself to that corrosive environment needs to be considered. However, in practice, discontinuities in the coating may occur during application or be produced subsequently by mechanical damage or by the corrosion of the coating itself. In these cases, the corrosion performance of the bimetallic system so produced is of major importance.

#### **4.04.2 Anodic and Cathodic Coatings**

A detailed discussion of galvanic corrosion between dissimilar metals in contact in a corrosive environment is given in the chapter on galvanic corrosion in this book. In the case of coating discontinuities, the effect of the anode–cathode area relationship and the nature of any corrosion products formed at small discontinuities may modify any choice made on strict considerations of general galvanic corrosion theory based on the potentials of the coating and substrate in the environment under consideration.

Thus, coatings which are anodic or cathodic to the substrate are both used in practice, but the former will provide sacrificial protection at a coating discontinuity, and the latter may stimulate attack on any exposed substrate. The sacrificial consumption of an

anodic coating at a pore or discontinuity results in a gradual increase in the area of substrate exposed and a corresponding decrease in the corrosion current density, which, in time, may become insufficient to maintain protection in the centre of the exposed area. The rate of sacrificial consumption of an anodic coating is reduced by several factors such as the resistance of the electrolyte solution within the discontinuity, blocking of the discontinuity by corrosion products, or the formation of protective films on the exposed substrate which may be encouraged by an increase of electrolyte pH by the cathodic reaction at the discontinuity. Under these circumstances, the life of the anodic coating will be prolonged.

Zinc and cadmium are both anodic to steel and provide sacrificial protection to the substrate when used as coating metals. On exposure to industrial atmospheres, zinc will protect steel for a longer period than cadmium, whereas in many marine or rural environments, cadmium provides a longer period of protection. Layton<sup>1</sup> attributes this difference in behavior to the nature of the corrosion products formed in the different environments. In industrial atmospheres, soluble sulfates of both zinc and cadmium are produced and are removed by rain so that corrosion can continue freely. Under these conditions, zinc, which has a more negative potential than cadmium in most environments, is a more efficient anode than cadmium and gives a longer period of protection to the substrate. In rural and marine exposure, however, the cadmium carbonates and basic chlorides that are formed are insoluble and corrosion is stifled to a greater extent than in the case of the more soluble zinc carbonates and basic chlorides, so tending towards a longer life with cadmium coatings.

When cathodic coatings are used, the sacrificial action is reversed, the substrate being attacked and the coating protected. This attack on the substrate can be highly localized and can lead to rapid penetration through the thickness of the metal. The effect is appreciably reduced by electrolyte resistance and by the stifling action of corrosion products, as mentioned above for anodic coatings, and the production of substrate corrosion products within the discontinuity can significantly decrease the corrosion rate and delay penetration.

Decorative coatings of nickel plus chromium are cathodic to steel or zinc alloy substrates, and with these protective systems, deliberate use may be made of discontinuities in the chromium topcoat where corrosion of the underlying nickel will occur. If the number of these discontinuities in the chromium

layer is greatly increased, the current density at each individual corrosion site is reduced; the penetration of corrosion through the thickness of the nickel layer is thus slowed down, and the period of protection of the substrate metal is prolonged.

In general, the choice between cathodic or anodic coatings will be governed by the service application. Where cathodic coatings are used, any attack on the substrate will be highly localized, leading to rapid perforation of thin sections with a consequent loss of functional integrity. Anodic coatings, on the other hand, will protect exposed areas of substrate metal by sacrificial action until the area exposed exceeds that, over which cathodic polarization of the corrosion reaction can be maintained, after which time the substrate itself will corrode freely.

With both anodic and cathodic coating systems, account must be taken of the extent to which the presence and nature of corrosion products on the surface may impair either the decorative aspects or the functional use of the article. For example, the presence of small amounts of corrosion products on the surface of gold-plated electrical contacts can markedly increase the electrical contact resistance and cause malfunctioning; the problem may be overcome by increasing the thickness of the gold deposit – thus reducing its porosity – or by interposing an undercoat of a more resistant metal to act as a barrier layer between the gold and the substrate.

Because of the many variables which can influence the corrosion reaction, the use of the e.m.f. series of metals to predict the behavior of galvanic couples in a given service environment can be hazardous and misleading. Numerous examples of coatings expected to act cathodically but have, in fact, been anodic have been reported in the literature,<sup>2-5</sup> and specialized lists of galvanic couples in different environments have been compiled.<sup>6-8</sup>

#### **4.04.3 Factors Affecting Choice of Coating**

Many factors are involved in the choice of coating material to be used for any particular application, and these will now be described.

##### **4.04.3.1 Resistance to the Corrosive Environment**

The principal difficulty in assessing the resistance of a coating material to a corrosive environment

lies in an adequate and accurate definition of that environment. Metals exposed to natural atmospheres will corrode at markedly different rates depending upon the degree of pollution present and a number of interrelated meteorological factors. Atmospheric corrosion rates for most of the metals in common use have been published by many authors and by official organizations such as the American Society for Testing and Materials (ASTM).<sup>9</sup> These tables may be consulted for general guidance but must always be used with caution by choosing data for environments that most nearly approach the service conditions concerned. However, purely local conditions can markedly affect the rate of attack. An example of this, in the authors' knowledge, involved the corrosion of galvanized-steel air-intake louvres on the roof of a building in a severe industrial environment; most of the louvres gave satisfactory service, but premature rusting occurred on those that faced in a westerly direction where the prevailing winds exposed them to additional chloride contamination picked up from a nearby river estuary. A detailed knowledge of both the macro- and microenvironmental conditions to be encountered is thus seen to be essential if the best choice of coating is to be made, and it is often desirable to make site inspections before recommending a coating system for a particular application.

When the corrosive environment consists of water or other liquids, the effect of the presence of minor constituents in the liquid as well as the degree of aeration and rate of flow must be taken into account.

##### **4.04.3.2 Practicability of Application**

It is essential to choose a material and a method of application that will provide a coating of adequate thickness with good coverage and distribution over the surface of the article.

Hot-dipped tin coatings are difficult to apply outside the thickness range of 8–38 mm,<sup>10</sup> and hot-dipped zinc coatings do not normally greatly exceed 50 mm in thickness. Hollow sections and excessively large articles may be impractical to handle by the hot-dipping process, and very thin sections may be subject to much distortion.

Electrodeposited coatings may range in thickness from about 0.1 mm to about 25 mm for decorative and protective purposes, though considerably greater thicknesses may be applied in the case of coatings for wear resistance purposes. The shape of the article to be plated greatly influences the thickness and coverage of the electrodeposit. Copper and nickel deposits

cover well and throw well into recesses, and leveling can be obtained during electrodeposition. Zinc gives good coverage but poor leveling, and chromium has a very poor throwing power leading to bare areas in deep recesses of the plated article. Precious metals, because of cost, tend to be electrodeposited in thicknesses of less than 1 mm, and at these thicknesses, porosity of the electrodeposit is a significant factor; acid gold electrodeposits tend to be less porous than the deposits from alkaline baths.

Sprayed metal coatings may be applied without limitations of size of the article to be processed such as may apply for hot-dipping processes, and the thickness and coverage of the coating can be readily controlled during application. Problems can arise, however, with applications involving complex shapes or hollow sections. Coating thicknesses are normally in the range 50–250 mm but considerably greater thicknesses may be built up for applications involving wear resistance, and diffusion heat-treatments may be subsequently applied in order to improve the resistance further. Sprayed metal coatings are of a porous nature and contain a high proportion of oxides produced by the method of application. In service, corrosion products may build up in the pores of the coating which can contribute materially to a stifling of the corrosion reaction, but even so, sacrificial protection of the substrate exposed at any coating discontinuities may still be maintained.

Cladding by pressing, rolling or extrusion can produce a coating in which the thickness and distribution can be readily controlled over wide ranges, and the coatings so produced will be completely free from porosity. Although there is very little practical limit to the thickness of coatings that can be produced in this way, the application of the process is limited to comparatively simple-shaped articles that do not require much subsequent mechanical deformation. Among the principal uses are lead and aluminum sheathing for cables, lead-sheathed sheets for architectural applications and composite extruded tubes for heat exchangers.

#### 4.04.3.3 Compatibility of Galvanic Coupling

Most of the published data on galvanic corrosion concern solid metal couples rather than bimetallic coating systems, and it is important to bear in mind that the same galvanic relationships do not necessarily apply in both cases; nevertheless, useful guidance can be obtained from the data for the solid-couple

systems exposed to suitable environments. Data have been reported<sup>11</sup> for combinations of metals commonly used in the electrical industry; couples involving plated brass, copper, and aluminum were exposed to a 1% salt spray and the corrosion currents (mA) were measured over a 1-week test period. The relative ratings in this test are shown in **Table 1**, and items of particular interest in this table are coatings of aluminum on either brass or copper that are unsatisfactory because of the active galvanic corrosion that occurs at discontinuities. If tin plating is used as an undercoat to the aluminum, corrosion of the substrate is prevented, but if tin is applied as a topcoat over the aluminum (particularly by means of the conventional zincate process) it is sufficiently porous to allow the aluminum to continue to function as an active anode and corrosion can continue.

**Table 1** Performance of various crimped metallic couples in 1% salt spray

---

The relationships given in [Table 1](#) apply to the specific environment quoted, and it must always be remembered that if the conditions are varied, even to only a small extent, different galvanic effects may be produced.

#### 4.04.3.4 Effect of Coating Process on Substrate Properties

The application of any coating process may affect the physical or mechanical properties of the substrate material and any such effects should be considered when choosing the type of coating to be used and its method of application.

With hot-dipping processes, apart from the risk of distortion previously mentioned, the high temperatures involved can produce annealing, for example, softening of brass and copper during hot-tinning. Furthermore, hard and brittle intermetallic-alloy zones are produced during hot-dipping as a result of diffusion of the liquid coating metal into the solid basis metal, for example,  $\text{FeSn}_2$  in the tinning of steel,  $\text{Cu}_6\text{Sn}_5$ , and  $\text{Cu}_2\text{Sn}$  in the tinning of copper – the extent and depth of the alloy formation depending on temperature and time of dipping. Thus, too long a dipping time in hot-dip galvanizing can lead to flaking during subsequent mechanical deformation.<sup>12,13</sup>

Evolution of hydrogen during some electrodeposition processes can cause embrittlement if it diffuses into the substrate; the effect has been reported for chromium and cadmium plating of high-strength steels,<sup>14</sup> and provision is made in relevant standards<sup>15,16</sup> for diffusion heat-treatments after plating to reduce the hazard. Alternatively, zinc or cadmium coatings may be applied by vacuum deposition, thus avoiding any embrittlement of the steel – a process of this nature having been developed by the Royal Aircraft Establishment, Farnborough. Cases have also occurred where cracks in a highly stressed electrodeposit have acted as stress-raisers, which initiate stress-corrosion of susceptible substrate metals.

Although the annealing effects of overheating are avoided when coatings are applied by metal spraying processes – provided that those processes are properly applied – it has been reported<sup>17</sup> that compressive stresses imparted to the substrate by the grit-blasting pretreatment can alter the fatigue properties of the material. Cladding involves extensive cold-working, which may necessitate annealing of the composite material before use.

#### 4.04.3.5 Coating Properties

A number of physical and mechanical properties of coating metals need to be considered when making a choice of metal to be used in a particular application.

Appearance, color, and brightness are important in decorative applications. Copper, zinc, cadmium, nickel, silver, and gold can be readily plated in a bright condition, while tin normally plates as a dull deposit but may be brightened by flash-melting after electroplating (flow brightening process). Aluminum and lead deposits are always dull, but reflective aluminum coatings can be produced by roll-cladding using highly polished rolls. Colors may range from the blue-white of chromium through yellows for gold or brass to the reds of bronzes. Reflectivity after polishing also varies with the coating metal, being very high for silver and rhodium and progressively decreasing in the order aluminum and palladium, tin, zinc, gold, iron, and lead.

Hardness, strength, and wear resistance are prime properties, not necessarily interrelated. For example, rubbing contact between two hard surfaces may produce more wear than with two soft surfaces, though, in general, rubbing contact between one hard and one soft surface causes wear in the softer material. However, mechanical design factors can alter this wear relationship so that the harder material wears to a greater extent, for example, the case of the rapid wear imposed on a steel record needle rubbing against a vinyl record surface. In general, the hardest deposits are those of chromium, nickel and rhodium; with iron, copper, zinc, cadmium, and silver in an intermediate hardness group; with tin, lead, gold, and indium being relatively soft.

Temperature resistance, that is, a combination of melting point and oxidation resistance, may be of prime importance. A general correlation exists between melting point and hardness since both reflect the bond strength of the atoms in the crystal lattice, and the preferred order of coating metals for use in high temperature applications as temperature is increased is silver, aluminum, nickel, rhenium, chromium, palladium, platinum, and rhodium.

The electrical conductivity of coatings is often of secondary importance since they are of thin section and are in parallel with a metallic substrate of larger cross section, which is generally a good electrical conductor. A more important property for coatings used as electrical contacts is surface hardness and the ability to remain free from oxide and tarnish films.

Thus, although aluminum has almost four times the conductivity of tin, it is often tin-plated to improve its electrical contact properties. Other coating metals commonly used for low-voltage applications are gold, tin/lead, silver, palladium, copper, rhodium, and nickel.

#### **4.04.3.6 Economics**

Economic factors are obviously of prime importance when choosing both the coating material and its method of application. Individual items in the economic balance sheet will vary not only with the material and the process but also with availability, local labor costs and factors unique to the design and use of the articles concerned. A further factor that frequently does not receive adequate importance in costing is the ease or otherwise of maintaining the finish to ensure an adequate and efficient service life for the component. In general, though with many exceptions, processing costs may range in ascending order from hot-dipping to plating, spraying, and cladding. The lowest cost group of metals includes zinc, copper, iron, and lead; the intermediate group contains nickel, tin, tin/lead, cadmium, and aluminum; and the highest cost group comprises silver, palladium, gold, and rhodium, though cost relationships may vary from time to time as a result of price fluctuations in response to supply and demand.

Experience in the application of metal-coating processes can materially affect economics. Thus, although it is possible to apply aluminum by electrodeposition, the process is difficult to operate and few metal finishers apply the process; the application of aluminum coatings by hot-dipping or by metal spraying is much more readily accomplished, and more of these types of installations are becoming available on the metal-finishing market.

### **4.04.4 Coatings in Practical Use – Overview**

In modern coating technology, the range of materials used is ever increasing and specific coatings may be chosen and applied, often by specially designed techniques, for particular applications. Details of the behavior of various specific metal coatings are given elsewhere in this book, but some general information on a number of the more commonly applied coating metals is as follows.

#### **4.04.4.1 Zinc**

This is an anodic coating material that may be applied by hot-dipping, metal spraying or electrodeposition, with a good corrosion resistance to most neutral environments, particularly when used in combination with chromate or phosphate passivation treatments. In most cases of atmospheric exposure, zinc will provide good protection to steel, particularly where any sulfur pollution is present, but in rural and pure marine environments the conditions of humidity and chloride pollution level can reduce the effectiveness of zinc coatings and make the use of cadmium more suitable, though the same degree of protection may often be achieved at lower cost by increasing the thickness of the zinc coating. Zinc is the preferred coating for steel used under immersed conditions in scale-forming waters or sea-water and, since it is less toxic than cadmium, it should be used in applications involving welding.

The life of zinc coatings is generally proportional to thickness and independent of the method of application, though it has been reported<sup>18,19</sup> that zinc electrodeposited from the sulfate bath gives a better performance than when deposited from the cyanide bath. Hudson<sup>20</sup> has reported lives for 42-mm-thick zinc coatings on steel ranging from 3½ years in a severe industrial environment (Sheffield) to more than 10 years in a rural environment (Llanwrtyd Wells), and Gilbert<sup>21</sup> quotes lives of 4–5 years in London, 9 years in Cambridge, and 18 years in Brixham.

#### **4.04.4.2 Cadmium**

Cadmium also provides a sacrificial coating to steel and gives better protection than zinc in applications where strong acids and alkalis may be encountered and those involving immersion in stagnant or soft neutral waters. It should be used in applications involving bimetallic contact with aluminum and in electrical applications where ease of solderability is important. Cadmium has a low torque resistance and should be used as a coating material in cases where bolted assemblies have to be frequently dismantled. It also provides better protection than zinc in enclosed spaces where condensation can occur, particularly when there is contamination by organic vapors.

Cadmium is more expensive than zinc. It is usually applied by electrodeposition in thicknesses up to about 25 mm and has a superior tarnish and stain resistance to that of zinc. As with zinc, the life

of cadmium coatings is proportional to thickness; Hudson<sup>20</sup> quotes a life of only 9 months at Sheffield for a 25-mm-thick coating and ~8 years for a 42-mm-thick coating exposed to a marine environment at Calshot.

#### 4.04.4.3 Tin

Tin is applied by hot-dipping or electrodeposition and has a similar corrosion behavior as that of zinc. Coating thicknesses are usually in the range 12–50 mm, and in the lower portion of this range coating porosity can be a factor to be taken into account (see discussions by Kochergin,<sup>22</sup> and Gonser and Strader<sup>23</sup>).

Tin coatings are widely used in the electrical industry because of their good contact properties and in the food industry because of low toxicity. In addition to pure tin coatings, a number of alloy coatings have been developed for special applications, for example, tin–lead (terne plate), tin–zinc, tin–cadmium, tin–bronze, and tin–nickel. Reference should be made to the relevant chapter in this book and to the publication by Britton<sup>24</sup> for data on the corrosion of tin and its alloys.

#### 4.04.4.4 Aluminum

Aluminum may be applied as coatings by metal spraying, cladding, hot-dipping and electrodeposition, though the last-named process is difficult to apply, and by far, the largest proportion of aluminum-coated metals are produced by the first two methods.

In atmospheric exposure to industrial environments, its corrosion rate is only about one-third that of zinc and the corrosion reaction is stifled by the tenacious oxide which is produced; nevertheless, it can frequently function as an anodic coating both for steel and for the less corrosion-resistant aluminum alloys.

Hudson<sup>20</sup> reported lives of about 4½ years for 38-mm-thick metal-sprayed aluminum coatings on steel exposed at Sheffield, and more than 11½ years for coatings 75 mm thick. Sprayed aluminum coatings (~125 mm thick) have also provided complete protection against exfoliation and stress corrosion to aluminum–copper–magnesium (HE15) and aluminum–zinc–magnesium (DTD 683) alloys in tests lasting up to 10 years in industrial and marine environments.<sup>25,26</sup>

#### 4.04.4.5 Nickel

Nickel has an inherently high corrosion resistance, particularly in chloride-free atmospheres, and is

widely used as a coating material in the chemical industry. When exposed to the atmosphere, rapid tarnishing and slow superficial corrosion occur; for this reason, nickel coatings are seldom used alone, but they are widely used as undercoats beneath bright chromium to give decorative and protective schemes for steel, zinc-alloy and copper-alloy consumer goods notably in the automobile and domestic hardware industries. Used in this way, corrosion of the nickel undercoat is confined to localized pitting that develops at discontinuities in the chromium layer and which will eventually penetrate into the substrate. Many special processing variations have been developed to improve the corrosion resistance of these composite coatings, and recommended systems are detailed in standards documents such as BS 1224 (1970).<sup>16</sup>

#### 4.04.4.6 Lead

Lead coatings are mainly applied by cladding and find principal use in the chemical industry for resistance to sulfuric acid, for cable sheathing resistant to attack by soils and in architectural applications where resistance to industrial atmospheres is particularly good. They rely for their protective action on the formation of insoluble corrosion products that stifle the corrosion reaction and lead to very long service lives, but the corrosion resistance is impaired when chlorides are present.

#### 4.04.4.7 Copper

Except in the case of certain decorative and electrical applications, copper is seldom used as a coating material in its own right owing to the rapidity with which it tarnishes, particularly in sulfur-polluted environments. Nevertheless, its atmospheric corrosion resistance is good owing to the development of the well-known green patina of basic copper salts, which give protection against further corrosion of the metal. When copper coatings are used for their decorative effect, the high luster and distinctive color are retained by applying a protective coating of transparent lacquer which may contain an inhibitor, for example, benzotriazole.

By far, the largest use of copper as a coating metal is in the form of undercoats to other protective schemes, such as the nickel plus chromium systems, where they offer great benefit by leveling the surface to improve the brightness of the finished article. Their role in the corrosion protection of the substrates is complex; they are themselves often preferentially attacked when overlay coatings are penetrated by

corrosion, and can stimulate enhanced corrosion of the substrate when penetration through their thickness occurs. On the other hand, however, in the case of coatings of bright nickel plus microdiscontinuous chromium, the use of a copper undercoat is known to improve corrosion resistance and to extend the period of protection of the substrate.<sup>27</sup>

#### 4.04.4.8 Chromium

Chromium is highly resistant to atmospheric corrosion, being almost inert in most atmospheres, and is therefore used as a thin, bright overlay to other coatings to retain decorative appeal for long periods. The thickness of these coatings, applied by electrodeposition, is normally in the range 0.3–1.3 mm. In the lower thickness range, the coating contains minute discontinuities which cannot be eliminated by increasing the thickness, since spontaneous cracking of the deposit occurs as the thickness builds up. The tendency to cracking of chromium electrodeposits is encouraged and put to good use by inducing cracking on a microscale by processing modifications. When this is done, the microcracked deposits so produced provide greater protection to nickel-plated steel and zinc-alloy substrates exposed to the atmosphere by increasing the area of nickel exposed at the microdiscontinuities, and thereby reducing the corrosion current density at individual corrosion sites with a consequent reduction in the rate of penetration through the nickel layer.

Chromium is also a very hard metal with excellent wear resistance, and so is widely used as a coating material for engineering applications. For these purposes, coatings are applied by electrodeposition which may be several millimeters thick. These hard engineering chromium coatings invariably contain fine cracks and fissures which can allow corrodents to attack the substrate, but this is not often a hazard in service and in many cases they are advantageous in providing a means of retaining lubricant on the working surface during use.

#### 4.04.4.9 Precious Metals

Gold and platinum, being highly noble metals, can provide highly corrosion-resistant coatings, but are rarely used for this application alone because of cost. Silver, though cheaper than gold or platinum, has a somewhat lower corrosion resistance since it is very prone to attack by sulfides, which cause dark tarnishing.

The principal use of gold is as a very thin coating about 0.05 mm thick for electrical and electronic applications. Because of the thinness of gold electrodeposits, porosity must be very carefully controlled since seepage of corrosion products from substrate or undercoat exposed at these pores can have serious adverse effects on both appearance and electrical properties of the composite. The porosity can vary with the thickness of the deposit (**Figure 1**), and with the type of plating bath and with its method of operation (**Figure 2**), and the phenomenon has been extensively studied by Clarke and many others.

#### 4.04.5 Recent Developments

The general principles of protection of metal substrates by metallic coatings are, of course, clear. Nevertheless, detailed considerations and particular aspects have received continued attention and some

**Figure 1** Log-log plot of gold-plate porosity against thickness for the conventional hot-cyanide gold-plating bath on copper substrate. The porosity was determined by the amount of copper (ppm) dissolved under standard conditions by an ammonia–ammonium persulfate test solution.

**Figure 2** Linear plots of the effect of current density on the porosity, expressed as ppm Cu, for three different gold-plating baths. The numbers next to each point show the actual average thickness (in mm) for each test. Bath A was a proprietary alkaline cyanide bath using silver as a brightener. Bath D was an acid gold bath containing cobalt and an ethylenediaminetetraacetic acid (EDTA) gold complex.

of these developments can be highlighted. Among general treatments, several books may be noted dealing with the coating spectrum and the theory of protection,<sup>28–30</sup> and a book on the testing of such coatings for product performance assessment in relation to quality assurance is also available.<sup>31</sup>

#### 4.04.5.1 Galvanic Coupling

This particular topic remains vital but often controversial especially when attempts are made to codify practice and opinion. The British Standards Institution have published a ‘Commentary on corrosion at bimetallic contacts and its alleviation,’<sup>32</sup> which represents an important first attempt to produce such a code. It lists 23 metals and alloys coupled to each other in three atmospheric and two immersed environments using a four-point subjective scale to describe behavior.

The shortcomings of such a code are mainly attributable to the limited number of environments considered because specific behavior is generally related to specific metal–electrolyte behavior which can result in substantial potential changes or even polarity reversals. A polarity reversal implies a large potential at one or both metal electrodes and may be attributed to two main factors:

1. onset of passivity on the more base (negative) metal, thereby raising its surface potential to more noble values;
2. solution complexants reacting with free metal ions of the corroding metal thereby lowering that metal’s corrosion potential.

The features of instances of such potential reversals have been described<sup>33</sup> and include tin coatings on steel in various foodstuffs, particularly acid fruits,<sup>34,35</sup>

cadmium coatings on steel in hard waters,<sup>36</sup> and zinc and aluminum for cathodic protection of steel in natural groundwaters.<sup>37,38</sup>

#### 4.04.5.2 Porosity

The study of coating porosity and its effect on corrosion rates continues to be an important subject and is generally directed at establishing the minimum thickness that can be allowed in a specification, related of course to a test/service corrosion environment. Porosity usually decreases exponentially with coating thickness (Figure 1 represents a relationship for part of the range only) and the minimum acceptable thickness can be defined according to 0, 0.5, 1.0%, etc. porosity level or to a threshold corrosion rate. The ability to measure porosity rapidly and precisely is therefore of importance and the whole subject has been critically reviewed by Clarke.<sup>39</sup> In many cases, the purpose of such testing is to separate effects on porosity of the coating process itself and the substrate preparation and roughness; the latter is often the aspect most susceptible to improvement.

The comparative tests for porosity are not very accurate or susceptible to statistical analysis. A number of electrochemical tests have been devised that are more sensitive and give better numerical data; such tests depend upon selection of a suitable solution for each coating–substrate combination but have shown considerable promise and commercial instruments have been marketed.<sup>40–42</sup>

#### 4.04.5.3 Environment Classification

All testing has to be related to environmental conditions whose characteristics must be defined. The relation of accelerated corrosion test condition to real service conditions is one aspect, while another is defining classes of environment and relating them to characteristic corrosion performance in order to produce useful specification guidelines. BS5493:1977 is an attempt to do this using four categories appropriate primarily to the United Kingdom (Table 2). Such a classification is clearly an oversimplification, but represents an important step in this particular direction.

#### 4.04.6 Alternative Coating Systems

The drive of financial economy has been manifest in terms of the need to establish alternative coating

**Table 2** Atmospheric corrosion environments<sup>a</sup>

Type 1	Nonpolluted inland	Rural areas, town suburbs
Type 2	Polluted inland	Industrial towns and cities
Type 3	Nonpolluted coastal	Type 1 but with marine spray
Type 4	Polluted coastal	Type 2 but with marine spray

<sup>a</sup>BS 5493:1977.

systems for particular applications based not on technical performance alone but also on cost saving and sometimes environmental or ecological considerations. Thus expensive metals may be challenged by cheaper metals and alloys, and cheap metals by non-metals. Every coating is under such economic pressure; some have withstood by reducing thickness, improving quality, and maintaining performance, but some have succumbed to the competition. Gold in particular has faced competition from brass electrodeposits in the cheap market, titanium carbonitride (CVD produced) for wear-resistant applications and Pd-Ni alloy electrodeposit for electrical connectors and contacts, each representing cost saving and improvement in selected properties.<sup>40–42</sup>

The desire to replace cadmium is generally attributed to its toxicity, both in terms of process pollution and product corrosion, and several alternatives are feasible: thicker zinc, tin–zinc alloy or tin–nickel alloy depending upon the precise application.<sup>43</sup> The demise of decorative nickel–chrome systems in the automotive industries of the world is partly due to cost and partly to market image, and not to technical performance where major improvements took place in the period 1960–1975 through the establishment of duplex nickel underlayers and microdiscontinuous chromium top layers. In the 1980s, the trend has been towards black finishes produced generally by powder-applied epoxy polymers.

A recent publication by Dini<sup>47</sup> provides a relatively novel text covering the material science of coatings and substrates.

#### 4.04.7 Multilayer Coatings

The use of layered electrodeposits has been practiced since the 1800s and has continued to the present day. The usual reason is for the use of a thick functional underlayer with a thin decorative or

cosmetic top layer; cost of a top layer such as gold is clearly an important factor. In the case of chromium, which is stressed and liable to cracking in service, the underlayers of nickel provide both protection against corrosion and resistance against crack continuation to the substrate. Nickel has been a common underlayer but recently concerns of nickel allergy with consumer-jewellery products have led to nickel-free underlayers, for example, Cu–Sn–Zn, being used. Such underlayers are usually of 1–20  $\mu\text{m}$  thickness, the top layer being 0.1–2  $\mu\text{m}$  thick. The history and wider development of such layered systems have been reviewed elsewhere.<sup>48–50</sup>

Underlayers for electrodeposits are deliberately added and are now an integral part of the coating specification. The origin has clearly been the need to increase corrosion resistance with a vulnerable top layer. The logic has been that if one layer can have a dramatic effect, perhaps many layers will continue the trend. The technique has been to use pulse techniques with specially formulated solutions and often potential, not current, control. In this way, an alloy plating solution of A and B can be pulsed to yield alternate layers of A-rich and B-rich layers. The length of the current pulses determines the layer thickness by a Faraday–Coulomb calculation. A number of layered electrodeposits have been studied, for example, Zn–Ni, Zn–Co, Zn–Fe, and enhanced corrosion resisting performance has been reported using layer thicknesses of  $\sim 1 \mu\text{m}$ . It has been noted that for steel, it is generally better to use an initial layer rich in zinc, and total thicknesses up to 50  $\mu\text{m}$  have been produced. (It should be noted that the alternative production technique of using two solutions with the substrate being moved from solution to solution is possible but is much less elegant because of the need to rinse between plating stations and the risk of passivation during the transfer.) Similarly, pumping alternate solutions and rinses through a fixed cell is possible but again rather inconvenient.

The ideal alloy system has often been stated to be Cu–Ni, as the alloy is one continuous FCC phase. This has also been well studied but for enhanced magnetic characteristics (giant magnetoresistive (GMR) applications). The solution requires a mild complexant, typically citrate or tartrate, in a simple acid formulation to be most effective.

The same principles have been adapted to attain enhanced coating hardness or strength for which thicknesses in the nanometer range are needed, and some promising results have been achieved. The nanometer thickness appears to exploit the grain

interfaces as dislocation ‘wave’ guides, thereby restricting ductility in depth direction.

These layering techniques have long been recognized as coating design opportunities and should always be part of any specification. Substantial development can be expected leading to more widespread incorporation into standard specifications.<sup>48–50</sup>

#### 4.04.8 Metal Whiskers

Metal whiskers are primarily, but not exclusively, found on electrodeposited coatings during product storage generally over relatively long periods of time. The phenomenon of such spontaneous metallic whisker growth can be identified, commonly, for metals such as tin, zinc, and cadmium. The first real documented evidence is from such growths emanating from cadmium-electroplated surfaces in capacitors in aircraft radios during the Second World War.<sup>51</sup> It soon became evident that such growths were more problematic on tin and perhaps, to a lesser extent, zinc surfaces. Whisker growths can vary in their morphology, with filamentous and nodular outcrops being the most common. Long filaments often pose the biggest potential problems because of their size and propensity and becoming detached from the metal surface from which they are growing. With tin finishes widely utilized in electronics, the chances of such growths causing reliability issues are obvious.

A single mechanism for whisker growth still eludes researchers. Many attempts have been made to provide such a theory: well known mechanisms include dislocation theories involving Frank–Read sources,<sup>52</sup> recrystallization,<sup>53</sup> two-stage dislocation involving climbing and gliding of dislocation loops,<sup>54</sup> and a cracked oxide theory.<sup>55</sup> With electronic devices reducing in size and intercomponent spacing becoming commensurately less, the threat from failures, particularly ‘shorting,’ is ever present. Until recently, one way of reducing the negative effects of tin whiskers was through alloying the metal with lead. However, with the advent of environmental concerns over the use of lead in electronics (and elsewhere) and the implementation of the so-called Pb-free solders, the occurrence of tin whisker growth may become more problematic. The continued use of tin finishes (particularly bright tin) is also problematic from a whisker growth viewpoint.

Recent investigations<sup>56</sup> have suggested that electrodeposited Sn–Mn alloys are capable of producing

**Figure 3** Scanning electron micrograph of tin whisker growth on an electrodeposited tin–manganese alloy coating.<sup>57</sup>

whisker growth after only a few hours at room temperature following coating formation (see [Figure 3](#)). Subsequent whisker growth was rapid and profuse.

Although the occurrence of cadmium whiskers may not be a major cause for concern due to its reduced usage (due to a poor environmental status), zinc whisker growth has come into prominence in recent years due to the metal's use as a protective coating in raised flooring in computer rooms. One particular incident in the United States involving computers in the Colorado Department of State's data center failing has been highlighted as a serious concern.<sup>58</sup> The occurrence of zinc-electroplated finishes in the vicinity of electronic components (e.g., on steel casings) must also be a cause for concern. The recent discovery of zinc whiskers on hot dip-galvanized surfaces<sup>59</sup> is a further indication of the potential size of the problem.

The perceived future problems associated with metal whisker growth, particularly on tin and zinc coated surfaces, are a cause for concern. The reasons for the occurrence of these types of growth need to be understood. At present, mitigation strategies are mainly based around the use of polymeric conformal coatings on areas of concern. The coatings do not preclude whisker growth underneath and, depending on the coating type and thickness, actual breaches of the coating layers have been reported.

For those wanting more information on whisker growth, a NASA website exists that is generally regarded as an excellent and comprehensive source of information.<sup>60</sup>

### 4.05.1 Introduction

Diffusion coating processes have been applied for more than half a century as a cost-effective method of improving the environmental resistance of a base alloy by enriching the surface in Al, Cr, Si, B, Ti, Zn, etc. The choice of surfacing material to be used depends on the base alloy and the final application of the component once surface-treated. For example, bolt stock are widely available zinc-coated using the sheradizing process to resist atmospheric and aqueous corrosion, while for high temperature applications, similar bolt materials could be chromized, that is, surface-enriched in chromium to produce a stainless steel surface layer. Probably the most exotic of these is the current practice to plate turbine blades with 5–10  $\mu\text{m}$  of platinum, diffuse and then vapor-aluminize to produce a platinum aluminide, a high temperature oxidation-resistant coating that may be also used as a

bondcoat for thermal barrier coatings for first-stage turbine blades in aero and industrial gas turbines.

Advanced applications include the surface engineering of materials and components for aerogas turbines, industrial gas turbines, medium speed diesels, automotive petrol engines, steam turbines, various power plant components, heat exchanges as well as catalytic reactors in chemical and petrochemical process plant. These illustrate the breadth of diffusion-coating applications.

From a surface engineering perspective, the final selection of the most suitable surface treatments/coatings must consider the following:

- (i) the operating temperature, both of the component in service and the part/component during coating manufacture and heat treatment;
- (ii) the service environment, duty cycle, and load-bearing capability of the treated components;
- (iii) the desired design life and the influence of the service temperature and duty cycle on long-term metallurgical stability, with respect to oxidation, corrosion and interdiffusion with the substrate;
- (iv) ease of manufacture, reproducibility, and the unit cost of the coating, compared to other manufacturing routes that may involve more costly corrosion-resistant alloys.

Obviously, loss of surface protection (passivation) can result in very high rates of attack to the substrate. In many cases, failure of a surface coating could make substrate attack worse, and may, on occasions, lead to catastrophic component failure. Even when not catastrophic, it is bound to be costly as a result of unplanned outage, downtime, and loss of production. Hence, the principal reason for applying a surface treatment of coating is to ensure that the coating is capable of operating efficiently throughout its design life. Diffusion coatings often are proven to be a cost-effective solution in this respect. Many diffusion-coating processes are so well established that international standards exist for their manufacture: for example, ASTM B 874-96 (2008) 'Standard specification for chromium diffusion coating applied by pack cementation'<sup>1</sup>; ASTM B 875-96 (2008) 'Standard specification for aluminum diffusion coating applied by pack cementation'<sup>2</sup>; and British Standard BS 4921 'zinc deposition using the "sherardising" process.'<sup>3</sup>

Pack-chromizing was in widespread use in the early 1950s<sup>4</sup> to increase the oxidation/corrosion resistance of low alloy steels. In the late 1960s, aluminizing was first used for the protection of superalloy gas turbine

aerofoils.<sup>5-7</sup> Aluminide diffusion coatings are now routinely applied to nickel-base superalloy blades and vanes used in the hot sections of gas turbines to enhance their resistance to high temperature oxidation and hot corrosion. Plain aluminides have provided cheap and cost-effective solutions to protect superalloy components within the high-pressure turbine of both aero and industrial gas turbines. As such, they are probably the most widely used coatings in service within the gas-turbine industry. There was renewed interest in siliconizing and silicon-modified aluminide diffusion coatings for high temperature service in the early 1970s<sup>8-11</sup> when novel solutions to the low-temperature hot corrosion problems associated with contaminants in marine turbine plants burning impure fuels were required. This interest continues with development of multifuel-capable plants that may be fired on gasified coal, biomass, or waste-derived fuels<sup>12</sup> and as coating methods to coat the internal cooling passages of turbine blades.<sup>13,14</sup>

These aluminizing, chromizing, and siliconizing processes result in enhanced corrosion resistance through the formation of protective thermally grown oxides of  $\text{Al}_2\text{O}_3$ ,  $\text{Cr}_2\text{O}_3$ , and  $\text{SiO}_2$  as discussed elsewhere in this book. It is also possible to produce diffusion coatings containing a combination of aluminum and chromium (chromaluminizing)<sup>15-26</sup> or aluminum and silicon<sup>8-13</sup> plus modified aluminides containing precious metals (Pt, Pd)<sup>6,27-34</sup> or reactive elements (Y, Hf and Zr).<sup>35-45</sup> The performance of these modified aluminide coatings will be discussed later in this chapter.

Diffusion coatings can be applied to hot gas components using a variety of techniques including pack cementation, slurry cementation, and metallizing. Comprehensive reviews of the methods of deposition of diffusion coatings are given in Goward *et al.*,<sup>5</sup> Goward and Boone,<sup>6</sup> Grisaffe,<sup>7</sup> Streiff and Boone,<sup>30</sup> Meier and Pettit,<sup>31</sup> Pichoir,<sup>46</sup> Goward,<sup>47</sup> Goward and Cannon,<sup>48</sup> Mevrel,<sup>49</sup> Nicholls,<sup>50,51</sup> and Pomeroy.<sup>52</sup> All diffusion coatings, whether depositing zinc vapor onto steels (sheradizing) for aqueous/atmospheric corrosion protection, or forming high temperature oxidation-resistant nickel or platinum aluminides, are formed as a result of two distinctly similar process steps, no matter what the manufacturing method used.

1. *The solute elements must be brought into contact with surface to be coated* In the sheradizing process (zinc deposition), the vapor pressure of zinc within the pack (it is a pack cementation-based process) is sufficiently high that no vapor-phase activator is

required; thus, zinc vapor generated in the pack directly deposits onto the component surface, ready for step 2, which is the 'diffusion' process. However, for most metallic systems, this is not the case; instead, an intermediate step is required, which is the production of a vapor species with a high solute metal content. This is most commonly achieved through the use of a halide salt, or salt mix, which may involve fluoride, chloride, or iodide species. Bromide species are almost never used for health reasons, although thermodynamically there is no reason why they should not be used. These halide additions are known as 'halide activators' in the industry.

2. *The solute diffuses into the component surface* Step 2 is a key stage in the manufacture of a diffusion coating. This diffusion step forms the surface alloy or intermetallic compound. The process temperature influences the rate of diffusion, which species may diffuse and the metallurgy of the surface compound that may form and is, therefore, a critical parameter in the processing and manufacture of diffusion coatings. This aspect will be explained in more detail using the 'pack-aluminizing' process as a case study (see [Section 4.05.2.1](#)). As well, time at temperature defines the thickness of the coating formed during this diffusion step.

Thus, the main differences between diffusion-coating process routes reflect the method by which solute and substrate are brought into contact. The time at temperature controls the degree of interdiffusion, establishes the concentration gradients that will develop from the surface to the interior of the coating and defines the various layers that may form as dictated by thermodynamic and kinetic considerations.

**Table 1** summarizes the currently available diffusion-coating process routes, together with a selection of elements that may be enriched into the substrate surface using these methods. Each of these process routes will be briefly reviewed.

#### **4.05.2 The Pack Cementation Process**

Pack cementation is still the traditional route used to apply diffusion coatings, with standard procedures established for chromium,<sup>1</sup> aluminum,<sup>2</sup> and zinc deposition.<sup>3</sup> For example, within the gas turbine industry, pack cementation was introduced into aero-engine service in 1957<sup>48</sup> and has been widely used to

coat turbine components since the mid-1960s.<sup>6,46–48</sup> The coatings produced were based on the formation of nickel or cobalt aluminides and this class of coating is still extensively used, probably satisfying some 75–80% of the current world market, for protecting turbine blades under aero, marine, and industrial turbine service.

In this process, the components to be coated are buried in a 'pack,' contained in a sealed retort. **Figure 1** shows a schematic diagram of a typical retort used to produce diffusion coatings, and **Figure 2** shows a photograph of the quarter-size commercial production facility at Cranfield University.

The retort is heated to the desired processing temperature under either an inert gas or hydrogen atmosphere to prevent oxidation. The exact process cycle, time, and temperature are dependent on the required coating, coating thickness and the subsequent substrate heat treatment. The pack contains a donor alloy that releases solute material at a known rate and hence determines the pack activity, a halide activator that dissociates during the process cycle and acts to transport the solute material from the pack to the component to be coated and an inert oxide diluent to prevent pack sintering.

Typical pack compositions used to produce a range of metallic coatings are given in **Table 2**. Of these, the three diffusion-coating processes that are most widely used are: 'sheradizing' to zinc-alloy coat many small steel parts in a wide range of manufacturing sectors from the building industries, through domestic white goods to many automotive parts to impart corrosion resistance<sup>3</sup>; 'chromizing' which may be used to coat a wide range of steel, stainless steel and nickel or cobalt-based superalloys to impart improved corrosion resistance for temperatures up to and sometimes in excess of 800 °C<sup>1</sup>; and 'aluminizing' which is widely used in the aero and industrial gas turbine sector to develop intermetallic surface layers that impart enhanced corrosion resistance, thermal stability and, for some applications, wear-resistant properties. The pack aluminizing process will be used as an example. The formation of aluminide coatings by pack cementation has been extensively studied, and details of the process and characteristics of the coating are well documented in the literature.<sup>3,5,6,15–18,20–31,35–42,46–52</sup>

##### **4.05.2.1 The Pack Aluminide Process**

During the aluminizing process, material from the pack is transferred to the component surface through the formation of intermediate volatile aluminum

monohalide gas, and as such the coating process is probably more accurately described as a chemical vapor deposition (CVD) process. Interdiffusion between the depositing aluminum and the substrate

**Figure 1** Schematic of a pack cementation facility.

**Figure 2** Pack cementation facility at Cranfield University: this is quarter size of an industrial production facility.

alloy results in the formation of the intermetallic coating, primarily NiAl, CoAl, FeAl, or TiAl depending on the alloy base, but containing, to a degree, most of the elements present in the base alloy, either in solution or as dispersed phases.

The CVD aluminizing process is best illustrated and described by the schematic in **Figure 3**, which describes the various chemistries involved during aluminum deposition and the formation of a nickel aluminide coating from an aluminizing pack. The processes involved in diffusion coating are complicated even when only nickel and aluminum are considered, as illustrated schematically in **Figure 3**. This behavior reflects the thermodynamic stability of the various phases in the nickel–aluminum binary system; the range of compositions for which each nickel aluminide phase is stable (which varies with process temperature); and the dominant diffusion processes in the newly (near surface) formed alloy due to the interdiffusion processes (which also depends on alloy composition).

The deposition rate and morphology of the coating depend on pack activity, process time and temperature. **Table 3** presents two pack compositions used in research at Cranfield to produce nickel aluminide coatings described in this section and illustrated in **Figures 4 and 5**. Coatings are classified as either ‘high activity,’ when inward diffusion of aluminum occurs or ‘low activity,’ when outward diffusion of nickel occurs. Thus the first pack composition in **Table 3**, with a higher aluminum content, is used at lower temperatures, 700–950 °C. This forms ‘low-temperature high-activity (LTHA)’ nickel aluminide coatings. (See **Figure 4** for a sample micrograph of this coating produced on the nickel-based superalloy CMSX4.) For this case, a surface layer of Ni<sub>2</sub>Al<sub>3</sub> forms and a further heat treatment is required to convert this brittle surface layer to NiAl. This step is usually combined with the heat treatment required

**Table 2** Typical compositions and deposition temperatures for halide activated pack cementation

Coating	Pack composition (wt%)	Deposition temperature (°C)
Al	1.2–2.7% Al, 0.8–1.2% NaF, bal. Al <sub>2</sub> O <sub>3</sub>	900

to recover substrate properties. This coating was deposited using an aluminizing pack containing 2% Al at 900 °C, and was heat-treated for 2 h at 1120 °C and then for 24 h at 845 °C. **Figure 5** illustrates, similarly, a nickel aluminide coating produced using a high temperature low-activity (HTLA) process. The HTLA process results in the outward diffusion of nickel from the superalloy to react with the depositing aluminum to form a monophase  $\beta$ -NiAl intermetallic surface layer. The pack composition (**Table 3**) used to deposit this coating has a lower aluminum content but is processed at high temperatures, 950–1100 °C.

From this simple illustration, it is clear that the properties and performance of an aluminide coating (or for that matter any diffusion coating) will depend upon the process methodology used, the substrate temperature and the subsequent heat treatment. For aluminide coating (also modified aluminizing coatings such as platinum aluminides, see **Section 4.05.4.1**), the critical difference in the processes reflects whether the coating is formed by inward aluminum diffusion, that is, inward grown diffusion coatings, or outward nickel diffusion, that is, outward grown diffusion coatings.

#### 4.05.2.2 Inward Growth Diffusion Coatings

When the aluminizing process parameters are chosen such that the aluminum activity at the component surface is high, then reaction between the nickel-based superalloy ( $\gamma$ -Ni +  $\gamma'$ -Ni<sub>3</sub>Al matrix) and the depositing aluminum forms a surface layer of  $\delta$ -Ni<sub>2</sub>Al<sub>3</sub>, over a subsurface layer of  $\beta$ -NiAl. This reaction is evident in the simple Ni–Al binary phase diagram, for process temperatures between 854 and 1133 °C (**Figure 6**), but may be further complicated by the addition of tertiary and quaternary elements which may modify the equilibrium phase structures.

In  $\delta$ -Ni<sub>2</sub>Al<sub>3</sub>, the diffusivity of nickel is near zero when compared to aluminum, which diffuses rapidly (Janseen and Rieck measured this diffusion rate as  $1.8 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$  at 600 °C)<sup>53</sup>; thus, the formation of a surface layer of  $\delta$ -Ni<sub>2</sub>Al<sub>3</sub> ensures that the coating growth results from the inward diffusion of aluminum. Phase equilibria require that beneath this layer  $\beta$ -NiAl is formed to accommodate the aluminum flux. This  $\beta$ -NiAl phase can react further with the inward diffusing aluminum to form more  $\delta$ -Ni<sub>2</sub>Al<sub>3</sub>.

**Figure 4** A nickel aluminide diffusion coating produced using a low-temperature high-activity (LTHA) pack cementation process.

**Figure 5** A nickel aluminide diffusion coating produced using a high temperature low-activity (HTLA) pack cementation process.

As a consequence of this inward growth process, slowly diffusing alloying elements within the substrate can be entrapped in the inwardly growing aluminide coating. Thus, a high-activity aluminide coating contains precipitates that are rich in W, Mo, Ta, Re, and Cr within the  $\beta$ -NiAl phase.

After aluminizing, the coated material is given a high temperature heat treatment (usually linked to the heat treatment necessary to recover the base alloys' mechanical properties). During this heat treatment, nickel is able to diffuse outward from the substrate, which results in the transformation of the brittle  $\delta$ -Ni<sub>2</sub>Al<sub>3</sub> phase into an aluminum-rich  $\beta$ -NiAl

( $\beta$ -NiAl has a wide solubility range for nickel and aluminum, from 46 to 74 at% Ni, 36 to 54 at% Al measured at 1100 °C).

#### 4.05.2.3 Outward Grown Diffusion Coatings

When the aluminizing process parameters are selected such that the aluminum activity at the component surface is low (low aluminum content in the pack, high process temperatures), then aluminum is deposited on the surface, but at a reduced rate, and nickel simultaneously diffuses outward to the surface. A  $\beta$ -NiAl surface layer now forms. For stoichiometric and substoichiometric NiAl (Al contents less than 51 at%),<sup>55</sup> the diffusivity of nickel in  $\beta$ -NiAl is much higher than that of aluminum. **Figure 7** presents the variation in nickel to aluminum diffusivity at 1100 °C as a function of the aluminum content of the  $\beta$ -NiAl phase.<sup>55</sup> Thus, this rapid nickel diffusion to the surface, coupled with the low aluminum activity at the surface, effectively holds the surface aluminum content at 51 at%. Hence, HTLA coatings are near-stoichiometric at the surface and nickel-rich within the subsurface  $\beta$ -NiAl phase that has formed. This structure ensures outward nickel transport and the outward growth of the coating microstructure. Another important outcome of this outward diffusion process is that slowly diffusing elements from the substrate are unable to diffuse to form significant concentration levels in the outwardly growing  $\beta$ -NiAl. The outer zone of this coating therefore appears much 'cleaner' and is free from such precipitates as observed in the inwardly grown, aluminum-rich coating formed at lower temperatures and higher aluminum activities.

### 4.05.3 Other Process Methods to Form Diffusion Coatings

#### 4.05.3.1 Slurry Cementation

Slurry-based diffusion coatings are commercially available, offering similar chemistries to those found in conventional pack cementation aluminide coatings. In slurry cementation, the coating materials and halide activator are blended as a slurry or particle-loaded paint system, using either an organic binder or a water-based emulsion. The slurry/paint system can be applied to the part to be coated through dipping or spraying at or near room temperature. The slurry spray is then cured onto the part through a low-temperature thermal treatment, typically around 200 °C. The cured pre-diffusion coating

**Figure 6** The Ni-Al binary phase diagram. Reproduced from Singleton, M. F.; Murray, J. L.; Nash, P. In *Binary Alloy Phase Diagrams*; Massalski, T. B., Ed.; ASM Materials Park: OH, 1990; Vol. 1, p 142.<sup>54</sup>

**Figure 7** Variation of  $D_{Ni}/D_{Al}$  with composition in  $\beta$ -NiAl at 1100°C. Reproduced from Shanker, S.; Siegle, L. L. *Met. Trans.* **1978**, 9A, 1467.

may contain only aluminum, aluminum + chromium, aluminum + silicon, or aluminum + chromium + silicon, depending on the final service conditions envisaged. After this overlay of binder, activator and reactive metals has been built up, the aluminum, silicon and other additions are diffused into the substrate by heating the precoated parts in a furnace at temperatures between 650 and 1100°C depending on the substrate to be coated and its final application. The temperature is chosen such that the coating material contained in the slurry reacts and interdiffuses with the substrate to form the final intermetallic coating. Reaction temperatures and the reaction chemistries are similar to those for pack cementation for halide-activated slurry systems. For systems not involving halide activation, diffusion occurs through direct contact between the molten aluminum or aluminum-silicon particles in the precured cement and the substrate to be coated.

Sermatech was an early protagonist of this form of coating, with Sermaloy J (**Figure 8**) – one of the first widely adopted slurry aluminide coatings – providing outstanding resistance to type II hot corrosion.<sup>56–58</sup>

**Figure 8** Micrograph of SermaLoy J.

This slurry aluminide coating forms a silicon-enriched outer layer containing  $\text{Cr}_2\text{Si}$  phases in  $\beta\text{-NiAl}$ , and provides oxidation and corrosion protection up to  $1000^\circ\text{C}$ .<sup>56–58</sup> Later, as engine technologies advanced and directional solidified or single-crystal alloys were more widely adopted, less chromium was available within the alloy to form  $\text{CrSi}_2$  (a critical phase within SermaLoy J)<sup>56</sup>; thus, joint research between Sermatech and Rolls Royce led to the development of SermaLoy 1515,<sup>59</sup> a multilayered structure slurry aluminide coating containing bands of  $\text{CrSi}_2$ . This variant is capable of providing hot corrosion protection to low-chromium-containing single-crystal alloys.<sup>58,59</sup> Other variants of the slurry aluminide process are now available commercially, including IP1041 developed by Indestructible Paints in the UK, and Ceral 10 by BWD Turbines Ltd. The latter uses a water-based slurry process to deposit the prediffused overlay coating prior to heat treatment and reaction to form the Si-containing aluminide coating. Most recently, slurry aluminide coating methods have been researched as a potential method for providing oxidation protection of Fe–Cr ferritic steels for steam power plants,<sup>60–62</sup> where the ability to form an iron aluminum oxidation-resistant coating at temperatures as low as  $650^\circ\text{C}$ , coupled with the capability to coat large steam turbine components at reasonable costs, makes the process commercially competitive.

#### 4.05.3.2 Fluidized Bed Techniques

Fluidized bed reactor-chemical vapor deposition (FBR-CVD) offers a cross between pack cementation and CVD processes. In addition, because of the

**Figure 9** Schematic of a fluidized bed chemical vapor deposition system.

excellent mixing and dispersion within the bed, efficient heat and mass exchange is ensured, giving uniform coatings on complex-shaped parts.<sup>63–65</sup> This allows uniform aluminide coatings to be produced on ferritic steels in relatively short times at temperatures below  $700^\circ\text{C}$ .<sup>66,67</sup> For FBR-CVD, the fluidized bed (Figure 9) consists of a mixture of the material to be deposited and an inert diluent, which forms the bulk of the fluidized bed and is most often alumina or silica. The halide activator is carried in vapor form by the fluidizing gas and is introduced into the fluidizing gas usually from a separate vapor generator or directly as HCl gas. This latter process is widely used in laboratory-scale systems by fluidizing the bed in a once-through cycle with HCl in the fluidizing gas.<sup>66,68</sup> In more commercial-size plants, the fluidizing gas is recirculated and the level of HCl to  $\text{H}_2$  in the feed gas adjusted to control the generation of the precursor vapor species. Also, when a vapor generator is used, it is possible to control the chemical activity of the active vapor supply to the fluidized bed reactor.

Components to be coated can be hung in the fluidized bed or supported on custom-designed fixtures, depending on their size. The chemistries in FBR-CVD has been extensively studied<sup>60–68</sup> and is similar to the LTHA aluminizing process of the pack cementation method, when aluminum powder is part of the fluidized bed medium. The primary differences are that the halide vapors are flowing, rather than diffusing, and that the carrier particle density is much lower in the fluidized bed than in the pack. Specifically, the gas flow rate must be greater than the minimum fluidization velocity; for a small laboratory experimental system, this would require argon

gas flow rates between 0.35 and 1.1 l min<sup>-1</sup>, with the fluidizing gas containing 5–30 vol% H<sub>2</sub> and 0.5–3 vol% HCl.<sup>66,68</sup> Given a reactor tube diameter of 3.5 cm in this laboratory scale system,<sup>66</sup> this equates to a linear fluidization velocity between 0.6 and 2.0 cm s<sup>-1</sup> when the fluidized bed has a height of 3 cm. Scaling to large fluidizing vessel sizes, therefore, requires high gas flows; for example, for a once-through cycle, a 35-cm-diameter bed would require gas flows in excess of 100 l min<sup>-1</sup>. Thus, large quantities of activator (HCl) and reactive gas (AlCl<sub>3</sub> in the case of aluminizing) would be lost to the scrubbing system. For these reasons, commercial fluidized bed systems use recirculating fluidizing gases, but this requires that the pumps, pipework and flow control equipment are designed for HCl service.

However, the benefits are that the use of a fluidized bed reactor for CVD deposition offers rapid and uniform heating of parts to be coated and good long-term stability (typically  $\pm 0.5\%$  variation in bed temperature, even when the bed is 15 m in diameter). These properties reflect the high heat and mass transport rates reported for fluidized bed systems,<sup>63,64</sup> improved process flexibility, lower capital and operating costs, precise process control, better environmental control, and the ability to automate the coating process.<sup>67</sup> Thus, in addition to aluminizing, fluidized bed systems have been proposed for chromizing, boronizing, nitriding, and carburizing.<sup>68–72</sup>

#### 4.05.3.3 Metallizing

Metallizing uses molten alkali and alkaline-earth fluorides as solvents for the electrolytic deposition of diffusion coatings. This process is well documented for the formation of alloy and intermetallic coatings following high temperature electrolysis in these molten salts.<sup>73–78</sup> The process is usually carried out at temperatures in the range 500–1200 °C in metallic vessels under inert gas, principally argon. The metallizing process is a specific method to deposit highly reactive metals that cannot be normally plated from aqueous solutions. Thus, aluminum, various refractory metals, the actinides, and many rare-earth metals can be deposited using the metallizing process. This capability to deposit refractory metals means that the metallizing process provides a coating route for niche-market applications. It has been used to manufacture protective refractory metal carbide coatings to protect components in contact with nuclear fuel<sup>73</sup> and to manufacture protective coatings for nickel cathodes (Ni<sub>3</sub>Nb) for use in molten carbonate fuel cells (MCFCs).<sup>76</sup>

The metallizing process was patented by N.C. Cook in the 1960s,<sup>79,80</sup> then at General Electric, to manufacture alloy and intermetallic coatings. Although process temperatures between 500 and 1200 °C are quoted, it is now acknowledged that many of the surface layers that are formed are thin unless processed above 800 °C.<sup>73</sup> The process consists of a galvanic cell where the anode is the reactive metal to be deposited and the cathode is the component to be coated.<sup>79–81</sup> Three modes of coating manufacture are now cited<sup>81</sup>:

1. Electrodeposition of a pure reactive metal onto the cathode, followed by interdiffusion of the metallic layers to form the alloy or intermetallic coating.
2. Metallizing, using a galvanic cell, as originally proposed by Cook.<sup>79,80</sup> In this metallizing process, interdiffusion occurs alongside the electrodeposition to form the alloy or intermetallic coating.
3. Thus, mode 1 can be used to deposit a surface coating from a molten salt in the temperature range 500–800 °C, which is subsequently diffused at higher temperatures or for longer times at the deposition temperature, whereas mode 2, the original patented metallizing process, requires higher process temperatures, in excess of 800 °C.
4. The third mode is similar to mode 1 but involves deposition of the coating at the ‘under potential’ for the alloy formation, following some interdiffusion process.<sup>81</sup>

In general, the purity of the fluoride solvents must be very high if a good and reproducible diffusion coating is to be formed. Any impurity cations in the melt will be codeposited.

Since metallizing reagents are electrochemically more reactive than the components to be coated, each coating material can only be deposited onto a specific group of metals to produce diffusion coatings. The more active the metal, the larger the scope of metallic substrates that can be coated. The most useful metallizing reactions include boriding, aluminizing, siliciding, titanizing, chromizing, zirconizing, and most recently the deposition of niobium and tantalum intermetallic coatings ‘niobiding’ and ‘tantalizing’ for the niche metal carbonate fuel cell markets.<sup>73,76</sup>

#### 4.05.3.4 Molten Salt Baths

Molten salt baths have been widely used for the direct thermochemical formation of diffusion coatings.

The formation of chromized coatings for corrosion protection and chromized, carburized, carbo-nitrided, nitrided, and borided diffusion coatings for wear protection are classic commercial examples of this form of diffusion coating manufacture.

In this process, components are treated in a bath containing a molten salt of the species to be deposited, which is then diffused into the component surface. For example, a mixture of chromous and chromic chlorides is used to form a 'chromized' diffusion coating.

Sodium and potassium cyanides are used in the salt baths for carburizing, carbonitriding, and nitriding. At a given temperature, the percentage of sodium or potassium cyanate generated in the bath determines whether a carburized or nitrided surface is produced. For low cyanate and high cyanide concentrations, carburization of the component surface occurs. At cyanate concentration around 10% and for temperatures between 750 and 900 °C, mixed carbonitride surface coatings are produced. Increasing the cyanate concentration to around 25% at temperatures between 500 and 750 °C results in the formation of a nitride-rich surface layer (all salt bath nitriding processes produce iron carbides as well as iron nitrides).

Thermochemical liquid-phase boriding processes are based on molten borax to which reducing agents such as ferroboration or boron carbide are added.

#### 4.05.3.5 Gas and Vapor Phase Chemical Vapor Deposition Processes

Gas and vapor phase processes offer the most diverse range of diffusion/chemical conversion coatings. The largest volume production of coatings based on gas and vapor phase CVD is used to combat wear. Pyrolysis of hydrocarbon gases, such as methane and propane, is used to carburize metal components. This method is generally cheaper to operate and more widely used for high-volume production than any other method aimed at producing a carburized surface treatment. The addition of ammonia to the hydrocarbon gas results in the formation of carbon nitride coatings; while pyrolysis of ammonia at temperatures between 500 and 525 °C produces a nitrided surface.

Chromized, boronized, siliconized, and aluminized diffusion coatings can also be produced by vapor decompositions but not generally at the commercial scale used for carburized and nitrided surface treatments.

In the corrosion field, especially high temperature oxidation and corrosion, chromizing and aluminizing are the most widely applied CVD coatings. Although, pack cementation (Section 4.05.2) is probably the most versatile and easiest-to-install small-batch process, the better process control of CVD – particularly the ability to codeposit metals and add small reactive element additions (see Section 4.05.4.4) – has seen an increased use of CVD and vapor phase coating routes to deposit high temperature corrosion-resistant coatings. A further advantage of these purely gas phase processes is the ability to coat internal cooling passages of the gas turbine blades, by directly feeding the vapor species into the existing cooling passages cast into the turbine blades.<sup>13,14,43,44</sup> Pressure 'pulse aluminizing'<sup>82</sup> can also be used to aid vapor transport into these narrow internal cooling passages.

(a) *The out-of-pack or over-pack process* operates in a manner very similar to pack cementation, except that the parts to be coated are suspended either above the pack or downstream from the pack (vapor generating) retort. The coating vapors ( $\text{AlCl}$  and  $\text{AlCl}_3$ , if aluminizing, depending on temperature and aluminum activity) are transported to the parts to be coated by an inert carrier gas. This approach results in a much cleaner coating, with no entrapped bed particles, but because of the longer path lengths for vapor transport, out-of-pack processes favor a low activity-type process, with outward coating growth and reduced coating deposition rates and thus longer processing times at any given temperature.

Figure 10, illustrates the modified retort used at Cranfield University to provide vapor phase coating deposition using an over-source deposition process. The process is entirely vapor phase using a process very similar to the Snecma vapor phase aluminizing process.<sup>83</sup> No longer is a powder pack required as a vapor source; instead, the source material is a crushed Cr–Al intermetallic alloy, which plays two roles: it lowers the aluminum activity creating a low-activity, outwardly grown aluminide coating, but does not melt at the desired processing temperatures. This means that it is no longer necessary to blend pack composition, and activation of the process only requires addition of the halide activator salt. Figure 11 illustrates a micrograph of the nickel aluminide coating produced using this vapor phase route, using NaF as the activator and a deposition temperature of 1050 °C.

**Figure 10** Modified retort to permit vapor phase aluminizing using an 'over-source' process.

**Figure 11** Micrograph of a nickel aluminide coating produced by the Cranfield vapor aluminizing process at a deposition temperature of 1050 °C.

- (b) Gas phase chemical vapor deposition process reaction gases are metered into the reaction vessel from external sources, see [Figure 12](#). Thus, the aluminum halide source gas is generated in an external vaporizer prior to being introduced into the reaction chamber. This enables better control over the reaction, since temperature, pressure, chemical activity and the flow path of the active gas can all be controlled independently. Further, separate vapor sources can be used for the external and internal aerofoil vapor circuits, permitting the outer gas-washed surface and the internal cooling passages to be coated with different compositions/thicknesses. With recent interest in adding active elements (see [Section 4.05.4.4](#))

and modifying coating compositions through codeposition, the ability to use a number of separated, controllable vapor sources permits more repeatable and reliable manufacture of the more complex coating formulations. Recent patents by Howmet have identified this approach as a method to ensure cleaner 'diffusion coatings.'<sup>84,85</sup>

#### 4.05.4 Modified Aluminide Coatings

From the foregoing, it is clear that the properties of an aluminum coating (or for that matter any diffusion coating) depend on the process methodologies used to deposit the coating, the substrate composition,

**Figure 12** Schematic diagram of Howmet's vapor aluminizing process using gas phase CVD. Reproduced from Warnes, B. M.; Punola, D. C. *Surf. Coat. Technol.* **1997**, 94–95, 1–6.

and the subsequent heat treatment. Thus, coatings produced by 'pack cementation,' 'out-of-pack' processes or 'chemical vapor deposition' will all differ in performance as discussed later in [Section 4.05.4.2](#). Similarly, a 'pack aluminide' coating whether a simple aluminide or modified aluminide on IN100,<sup>83,86,87</sup> IN738,<sup>84,88–91</sup> IN792,<sup>34</sup> CMSX4,<sup>31–34,52</sup> AM1,<sup>83</sup> Rene 80,<sup>31</sup> or PWA 1480<sup>31</sup> would all be expected to behave differently. Typically, a 'high activity' pack aluminide coating (e.g., PWA73) would be 50  $\mu\text{m}$  thick (65  $\mu\text{m}$  including the interdiffusion zone), with an aluminum content in excess of 30 wt% in the near-surface region of the diffusion coating.<sup>33,34</sup> Such pack aluminide coatings offer satisfactory performance for many aviation, industrial and marine applications and provide satisfactory performance at relatively low cost. It is a mature technology first patented in 1961 and in wide service for protecting turbine blades and vanes since 1970 (as cited by Goward<sup>48</sup> while reviewing the historical perspective of high temperature coatings). However, at temperatures above 1050  $^{\circ}\text{C}$ , especially under cyclic conditions, or under severe hot corrosion, these simple aluminide coatings offer limited protection. Thus, from the 1970s onwards, developments in diffusion coating technologies included modification of the aluminide coatings.

Modified aluminides have been fabricated using one of the following techniques:

1. codeposition of elements from the same pack;
2. codeposition from two separate vapor sources (generated using the over-pack process or by CVD);
3. pretreatment of the superalloy before pack-aluminizing (or vapor phase aluminizing), for example, chromizing a part prior to aluminum;

4. deposition of a metallic layer, using electroplating or PVD (physical vapor deposition) techniques, prior to aluminizing, for example, a platinum-aluminide coating produced by depositing platinum onto the superalloy prior to the aluminizing treatment.

Alloy additions may include chromium,<sup>15–26,92–97</sup> silicon,<sup>8–13,56–58</sup> platinum,<sup>6,27–34,50,93,100–113</sup> and, most recently, various reactive element additions, including Hf, Zr, Ce, and Y.<sup>35–45</sup> Probably the most significant advance in this area was the development of the platinum-modified aluminum class of coating. The first commercial coating in this class was designated LDC-2 and was produced by electrodepositing a thin layer of Pt, followed by a pack-aluminizing treatment at 1100  $^{\circ}\text{C}$ .<sup>84</sup> Since 1970, this process has been licensed to many manufacturers who produce their own variants of this basic coating design, see [Figures 14–16](#) for examples. Platinum aluminide coatings have much improved high temperature performance over diffusion aluminides. Although typically 2–3 times costlier than a conventional pack aluminide coating, they may last up to 3 times longer, depending on the service environment and duty cycle. Much of this most recent work results from the recognition in the 1990s that platinum-modified aluminide coatings develop stable alumina scales and hence perform as a useful bondcoat for EB-PVD thermal barrier coatings (see [Section 4.05.4.1](#)).

#### 4.05.4.1 Platinum Aluminide Coatings and Bondcoats

Most commercial platinum aluminide coatings are manufactured by first electroplating typically 5–7  $\mu\text{m}$

of platinum onto the component surface, and then heat-treating the platinum-plated component to diffuse the platinum into the nickel-based superalloy surface, prior to aluminizing. The quantity of platinum varies from one manufacturer to another, with between 2 and 10  $\mu\text{m}$  in common usage. There is a commercial drive to reduce the platinum thickness to produce platinum-lean platinum aluminides with the performance enhanced by adding various reactive elements<sup>114</sup> (see Section 4.05.4.4). Equally, platinum need not be electroplated, and in a drive to develop 'clean' coating methods, alternative routes involving the PVD (physical vapor deposition) of platinum have been investigated, although electroplating methods are still the most widely used in industry.

Both high-activity and low-activity aluminizing may be used following platinum plating and its partial diffusion into the component surface. Thus, platinum aluminide coatings have been produced commercially using pack cementation, out-of-pack or over-pack processes and gas phase CVD (Warnes and Punola<sup>84</sup> provides a comparison of pack cementation and gas phases CVD for the production of

platinum aluminum coatings, and will be discussed in more detail in Section 4.05.4.2 on the role the coating process has on introducing impurities into the coating). Depending on the initial Pt thickness, its diffusion heat treatment and the mode of aluminizing, together with aluminizing parameters, a range of microstructures can be produced. The four most widely found structures are illustrated schematically in Figure 13. Thus the platinum aluminide coating can be single-phase ( $\beta$ -PtNiAl) platinum aluminide, for example, MDC150, MDC150L, or CN91 (see Figure 14 for example), or a two-phase platinum aluminide, classified into one of three microstructures: an outer zone consisting of a two-phase  $\beta$ -PtNiAl + PtAl<sub>2</sub> over an inner  $\beta$ -phase NiPtAl layer (an RT22 type), an outer zone of PtAl<sub>2</sub> over an NiPtAl  $\beta$  phase and a structure that is a mix of both these morphologies, consisting on an outer PtAl<sub>2</sub> layer, a middle zone of PtAl<sub>2</sub> +  $\beta$  PtNiAl, and an inner layer of  $\beta$ -NiPtAl.

Figure 15 illustrates the single phase  $\beta$ -PtNiAl microstructure manufactured using the coating facilities at Cranfield to produce a microstructure similar to CN91. The coating was produced by PVD

**Figure 13** Schematic microstructures of platinum-modified diffusion coatings.

**Figure 14** Micrograph of MDC150L platinum aluminide coating, produced by a gas-phase CVD process.

**Figure 15** Single-phase platinum aluminide coating (CN91 type).

deposition of platinum to a thickness of 7 μm, heat-treated, then over-pack aluminized at 1080 °C using a HTLA process.

**Figure 16** illustrates a two-phase  $\text{PtAl}_2 + \beta\text{-PtNiAl}$  microstructure manufactured at Cranfield. The platinum layer was again 7 μm by PVD and heat-treated, but the aluminizing treatment was a high-activity pack aluminizing process at 970 °C.

During service at elevated temperatures (above 850 °C), the microstructure of the coating continuously evolves with time and temperature. The effect of ageing up to 4000 h at 1000 °C and 1050 °C on the microstructure of RT22 is illustrated in **Figure 17**, which demonstrates the effect of platinum diffusion into the substrate: aluminum

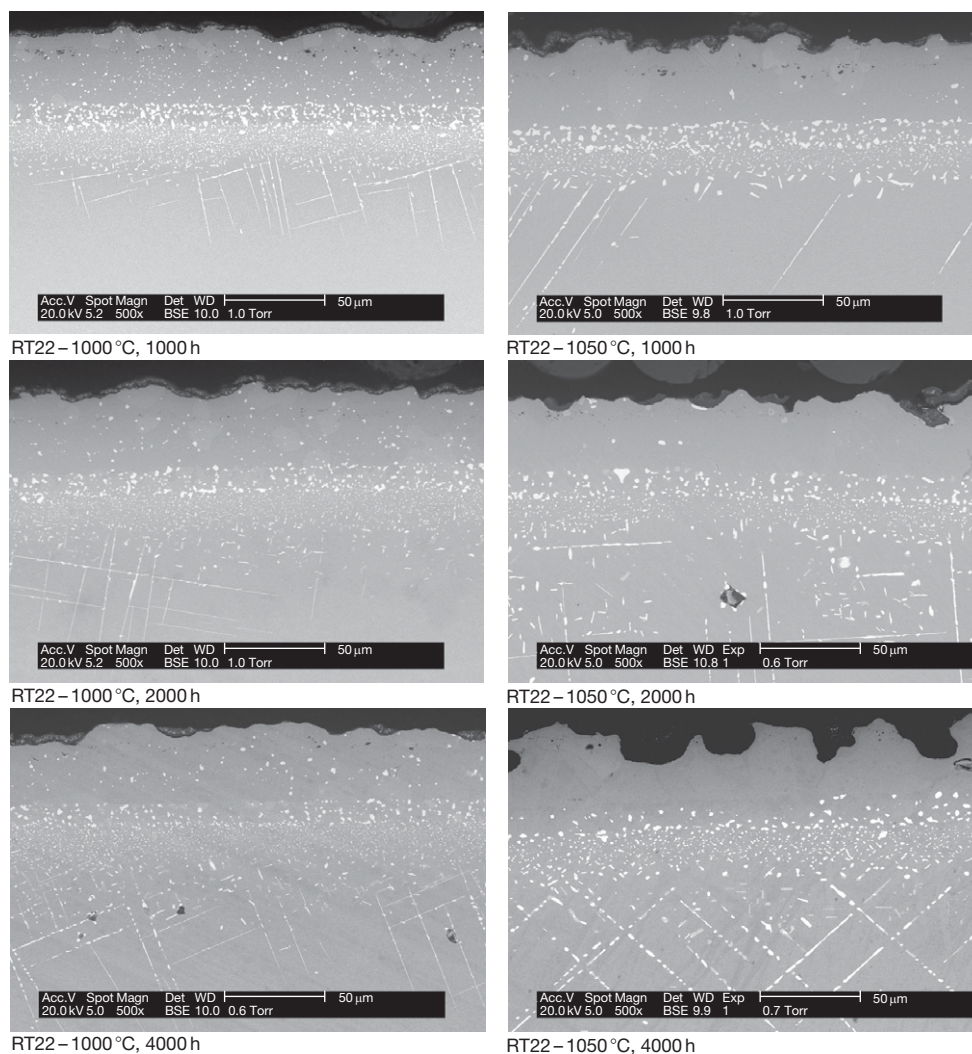

**Figure 16** Two-phase platinum aluminide coating (RT22 type).

consumption by interdiffusion, oxidation, and the formation of various TCP precipitate phases containing refractory metals that have diffused into the platinum aluminide coating from the substrate.

#### 4.05.4.2 The Role of Impurities Introduced in Coating Manufacture

As discussed above, the way the coating is made as well as its final microstructure and composition can have a major influence on its performance and lifetime. With the aim of increasing oxidation life, Howmet<sup>84</sup> undertook a research program on the role of tramp impurities, introduced through the manufacturing process, on the cyclic oxidation lifetime of platinum aluminide coatings.

**Figure 17** Influence of long-term exposure on the microstructured degradation of the platinum aluminide coating RT22 at 1000 °C and 1050 °C.

This research investigated three alternative routes to manufacture a platinum aluminide coating deposited onto an IN738 nickel-based superalloy substrate. A common platinum plating method was used for all three platinum aluminides with difference only in the method of undertaking the aluminizing process. The processes were:

- LDC2E: a high aluminum activity pack cementation process, resulting in inward aluminum diffusion.
- MDC-150: a high aluminum activity, gas phase CVD process. An inwardly grown aluminide coating activated by  $\text{AlCl}_3$  generated external to the CVD retort.
- MDC-150L: a low-activity aluminide coating formed by outward nickel diffusion using the

gas phase, and external  $\text{AlCl}_3$  vapor source used to manufacture the MDC-150 coating.

Four tramp impurity levels were studied: B, P, S, and W. Three of these perceived harmful impurities come from the IN738 substrate alloy, namely B, S, and W, while the fourth (P) comes from the electroplating of platinum. [Table 4](#) illustrates the chemical analysis results.<sup>84</sup>

The four elements were selected because they could be introduced into the coating from three potential sources:

- the superalloy substrate: W, S, P, and B;
- the platinum plating process: P;
- the aluminizing process: S and B.

**Table 4** Bulk chemical analysis of coated IN738 foils

<i>Element</i>	<i>As platinum plated</i>	<i>LDC2E coated</i>	<i>MDC 150 coated</i>	<i>MDC 150L coated</i>
B	120	140	150	50
P	450	440	390	140
S	6	7	8	5
W	23 900	23 000	5700	1300

All concentrations are in parts per million by weight (ppm).

Source: Warnes, B. M.; Punola, D. C. *Surf. Coat. Technol.* **1997**, 94–95, 1–6.

Bulk chemical analysis of the coated foils reveals some interesting results. First, the ‘low activity’ CVD aluminizing process is able to ‘clean up’ the coating with respect to these tramp additions, reducing significantly the level of each tramp element addition. Second, the high-activity aluminide processes increase the level of B and S in the coating over that of the ‘as-plated’ condition. For the pack aluminide process (LDC 2E) this was thought to be due to transfer of S and B from the source alloy (analysis of the aluminum–chromium source gave 22 ppmw S and 310 ppmw B); however, the high-activity vapor aluminizing process used 99.999 wt% Al as a source in the  $\text{AlCl}_3$  vapor generator.

Further microprobe studies showed that in the MDC150L coating, where the low activity aluminide appeared to clean the process, concentrations of impurities peaked in the interdiffusion zone and dropped in the diffusion coating surface, with levels at the surface significantly below that found in the IN738 substrate. Such behavior is consistent with the aluminizing process removing contaminants from the surface as a result of a gas–solid surface reaction.<sup>84</sup> In the ‘as-coated’ condition, both ‘high activity’ processes (LDC-2E and MDC-150) had a two-phase ( $\text{NiPtAl} + \text{PtAl}_2$ ) microstructure, while the MDC-150L had a single-phase  $\text{NiPtAl}$  microstructure. After solution heat-treatment of the IN738, all of the coatings were single phase, but varied in thickness and surface aluminum and platinum contents: LDC-2E 74  $\mu\text{m}$  thick, 20.0 wt% Al, 30.6 wt% Pt; MDC150 88  $\mu\text{m}$  thick, 23.2 wt% Al, 22.6 wt% Pt; MDC-150L 77.5  $\mu\text{m}$  thick, 19.5 wt% Al, 19.0 wt% Pt (the quoted thickness included the coating and interdiffusion zone).

Cyclic oxidation tests at 1100 °C (50 min at temperature, 10 min cooling) on these three coating variants (Figure 18) showed that the MDC150L (low-activity aluminide, formed by outward nickel diffusion) had a significantly longer life. The lifetime was defined as the time to ‘zero crossover’ (see Figure 21 to illustrate this definition).

A very important conclusion from this study is that minor tramp element contaminants can influence the oxidation cyclic life, with higher contaminant levels lowering the life. Even more important is the fact that the choice of processing route can influence the level of tramp contaminants in the coating and that through a correct choice of processing it is possible to ‘clean up’ the coating, thereby, giving between 20% and 40% improvement in lifetime, using rounded numbers.

#### 4.05.4.3 Chromium- and Silicon-Modified Aluminides

To combat hot corrosion, additions of chromium<sup>56,57,92–97</sup> and silicon<sup>98–100,103</sup> were extensively researched in the 1970s and 1980s. Research into the influence of these additions still continues as additions to both standard aluminides and platinum-modified aluminides, especially when considering coating on the latest third- and fourth-generation low-chromium-containing single-crystal alloys.

This early research plus service experience has shown that chromium additions to aluminide coatings offer little advantage over standard aluminide coatings under high temperature oxidation conditions. However, chromium additions are found to be beneficial and offer improved performance in industrial and marine turbine applications burning high-sulfur fuels.<sup>15,19,20,46,49,94,97</sup>

Additions of silicon are also known to improve hot corrosion resistance, but may also benefit the high temperature oxidation performance of aluminide coatings. Since the early work in the late 1970s and early 1980s, a number of researchers have investigated the role of Si, both for high temperature oxidation resistance and hot corrosion resistance, in diffusion aluminide coatings.<sup>10,56–114</sup> The possibility of using silicon aluminides for protecting internal cooling passages has also been investigated.<sup>14,115</sup>

The most commonly used silicon aluminide is the commercial coating SermaLoy J, a  $\text{CrSi}_2$ -dispersed

**Figure 18** Cyclic oxidation lifetimes for various platinum aluminide coatings on IN738 at 1100 °C: The cycle is 50 min at temperature, 10 min cool, cycled hourly, with failure defined as the time to zero mass gain cross over (the cyclic lives were calculated from data present in Warnes and Punola).<sup>84</sup>

$\beta$ -NiAl diffusion coating.<sup>11,56–58,100</sup> The microstructure of this coating is illustrated in **Figure 8**. Sermaloy J is manufactured using a slurry aluminizing process route. At about 10 wt% silicon in a diffusion aluminide coating, the silicon aluminide coating provides unsurpassed resistance to type I and II hot corrosion.<sup>11,58,100</sup> It is, however, somewhat brittle and this limits its use for internal cooling passage applications at this level of silicon content. Later, as engine technologies advanced and single-crystal alloys were widely adopted, with lower chromium contents, there was less chromium available within the alloy to form the  $\text{CrSi}_2$  precipitates – a critical component of Sermaloy J<sup>56–58</sup> – thus a research program between Sermatech and Rolls Royce led to the development of Sermaloy 1515. Sermaloy 1515 is a layer-structured slurry aluminide diffusion coating containing bands of  $\text{CrSi}_2$  precipitates as illustrated in **Figure 19**. Sermaloy 1515 is, thus, specifically designed to provide hot corrosion resistance on low-chromium-containing single-crystal alloys.<sup>56,58,59</sup>

For cooling passage applications,<sup>115,116</sup> this silicon content of the aluminide has to be reduced such that it does not impact on the alloy mechanical performance but must be sufficiently high to confer good oxidation and hot corrosion protection. Reducing the silicon level to between 1 and 2 wt% meets this criteria. Testing coatings with silicon levels in this range under Cyclic oxidation at 1100 °C and 1 h hot dwell

**Figure 19** Sermaloy 1515 silicon aluminide coating on IN738 produced by a repeat slurry aluminizing process route.

cycles gives a lifetime of 280–320 cycles.<sup>116</sup> A result superior to that of a standard aluminide (HTLA aluminide) was obtained, for which the cyclic lifetime varied between 25 and 120 cycles, but was inferior to a platinum aluminide. The worst of the platinum aluminides in **Figure 18** gave a lifetime of 1174 cycles under similar test conditions.

Under hot corrosion conditions, both type I and type II, this coating with 1–2% silicon addition was superior to a conventional aluminide, lasting approximately twice as long to through coating penetration, but was inferior to the performance of Sermaloy J containing a higher silicon content.

#### 4.05.4.4 Reactive Element-Modified Aluminide Coatings

There has been continued interest in the ability to incorporate active elements in  $\beta$ -NiAl to improve cyclic oxidation resistance through enhanced scale adherence. The benefits of oxygen-active elements are well documented in the literature; for example, yttrium levels below 0.5 wt% are widely added to commercial overlay coatings to reduce oxidation rates and improve scale adhesion. Even in the development of the earliest MCrAlY coatings this was recognized.<sup>48</sup> The most recent MCrAlY overlays are far more complex and may contain multiple active elements, including Y, Si, Hf, Zr, Ta, etc.<sup>11,28,99,117–120</sup> and even minor addition of precious metals.<sup>31,104–106,117</sup>

For systems based on  $\beta$ -NiAl, the systems are far less advanced, with few reactive-element-modified diffusion coatings commercially available.<sup>43,44</sup> Most of the research has been on model alloys<sup>36,121–125</sup> and

**Figure 20** Yttrium-modified aluminide 'over pack' CVD coating.

in particular on the roles of hafnium, zirconium, and yttrium. Some research papers have considered the incorporation of reactive elements as part of the CVD process.<sup>35–44</sup> Early published work by Bianco and Rapp<sup>35–37</sup> introduced reactive elements into the CVD process such that codeposition of the reactive element with the aluminide occurred. This approach has also been adopted in the one published commercial application in which Howmet used multiple vapor sources to blend the vapor phase environment from which the codeposited active-element-modified aluminide is formed.<sup>84,114</sup> In the work of Kim *et al.*,<sup>42</sup> a yttrium-modified aluminide was formed by first pack-aluminizing the substrate alloy (in this case IN738) and then depositing a thin layer of yttrium by electron beam evaporation, prior to heat treatment to interdiffuse the coating. It is only recently that yttrium-modified aluminide has been able to be produced using a simple pack cementation or the 'over-pack' CVD process.<sup>126</sup> **Figure 20** illustrates a micrograph of a yttrium-modified aluminide using the 'over-pack' CVD process developed at Cranfield. **Figure 21** compares the cyclic oxidation performance (1100 °C, 1 h hot dwell) of various aluminide and modified aluminide coatings produced using facilities at Cranfield University on an IN738 substrate alloy. The improvement in performance of the modified aluminides can be seen relative to that for an uncoated IN738 alloy and IN738 aluminized using a high-activity aluminide process. The uncoated alloy failed (zero net mass gain crossover point) at  $30 \times 1$  h cycles and the high-activity aluminide failed at  $620 \times 1$  h cycles, while the monophasic (high temperature, low activity) platinum aluminide and the

yttrium-modified aluminide did not fail (zero net mass gain crossover) at the end of the test ( $900 \times 1$  h cycles at 1100 °C). Extrapolation of the oxide spalling regime leads to an estimated life of  $1000 \times 1$  h cycles for both the platinum aluminide coating and the yttrium aluminide coating, based on the zero net mass gain crossover point. However, whereas the platinum aluminide coating started to spall at  $170 \times 1$  h hot cycles, the yttrium aluminide did not start to spall until  $800 \times 1$  h hot cycles at 1100 °C.

#### 4.05.5 Mitigating Substrate Alloy Interdiffusion Effects

As is evident from the earlier sections reviewing diffusion coating manufacture, all diffusion coatings must involve an underlying material, usually the substrate alloy, as part of the coating manufacturing process. It is for this reason that similar diffusion coating processes but on different substrate alloys produce different coating systems, and hence the lifetimes of such coatings, be it oxidation, cyclic oxidation or high temperature corrosion, will be influenced by alloying additions diffusing out from the substrate into the coating. Some elements can be beneficial, for example Cr, Si, Hf, Y, etc., while others are clearly detrimental, such as W, Mo, V, possibly Ru, either to the cyclic oxidation or hot corrosion performance of the coating.

One of the benefits of the high temperature low-activity aluminizing processes is the reduction of refractory metals, such as W and Mo, that move outward from the substrate into the coating owing to the fact that the coating is formed as a result of outward nickel transport, and the refractory metals diffuse outward much more slowly than nickel. This observation highlights one way of mitigating the detrimental effects of alloy additions and tramp elements moving from the substrate into the coating during manufacture: that is, to precoat the alloy with some form of temporary or partial barrier (nickel plating the substrate, for example, in its simplest form) prior to aluminizing. A second is to deposit an MCrAlY overlay coating as a partial diffusion barrier and then aluminize the MCrAlY overlay coating.

Commercially, variants on this approach have been used. General Electric has a patented process for over-aluminizing an MCrAlY coating, previously sprayed or EB-PVD-deposited onto the alloys surface. GT29+ and GT33+ are examples of the 'over-aluminized' version of GT29 (Co28Cr6Al0.5Y) and

**Figure 21** Cyclic oxidation performance of modified aluminide coatings, produced at Cranfield University: 1100 °C, 1 h hot dwell cycles (data from Long and Nicholls and Nicholls and Wing).<sup>116,126</sup> (Note: ↑ equals point of zero crossover for a LTHA aluminide.)

GT33 (Ni22Cr9Al0.5Y). These coatings are used on blades and vanes of GE industrial engines, models 7/9EA and 7/9FA/FA+,<sup>127</sup> making the performance of the coating less dependent on the substrate alloy chemistry from an oxidation and/or corrosion perspective. These dual-layered over-aluminized MCrAlY alloys provide surface layers with up to 25 wt% Al for good oxidation resistance, while the MCrAlY base confers better hot corrosion resistance because of the higher levels of Co and Cr.<sup>127</sup> Additionally, the incorporation of Y from the MCrAlY into the surface aluminide layer confers improved scale adhesion to the alumina scale, improving the cyclic oxidation resistance of this dual layer coating. The surface aluminide layer is brittle, however, and the higher ductile to brittle transition temperature (DBTT) makes the surface layer prone to thermo-mechanical fatigue (TMF) cracking during start/stop cycling. The more ductile MCrAlY underlayer can blunt these cracks, thereby, limiting their propagation into the substrate. The presence of an outer aluminide layer on a CoNiCrAlY basecoat (GT33+ compared to GT33) can lower the TMF life by a factor of 2.5 at high strain ranges, while at low strain ranges (0.45%ε), the TMF lives are comparable.<sup>127</sup>

Howmet now also offers these duplex MCrAlY + aluminide coatings.<sup>128</sup> However, they claim that by using low-activity aluminizing in addition to

the MCrAlY alloy, they can further improve the oxidation performance when compared to a similar coating made by pack cementation.

#### 4.05.5.1 Smart Coating Concepts

Smart overlay coatings<sup>129–131</sup> are functionally gradient coating systems designed to provide high temperature oxidation and corrosion protection over a wide range of operating conditions. The SMARTCOAT concept is a natural extension of the ideas embodied in GT29+ and GT33+, the over-aluminized MCrAlYs, which involves surface-treating a base overlay coating using diffusion coating processes to obtain improved performance and durability, but now extended to produce a chemically graded structure that can provide both high temperature oxidation protection as well as more optimized protection to type I and II corrosion. Thus, the SMARTCOAT design consists of an MCrAlY base coating, which can be deposited by any spray deposition method (air plasma spray (APS), Vacuum plasma spray (VPS), and high velocity oxy-fuel (HVOF)), by occluded electroplating or by EB-PVD, which is overcoated with successive layers to produce the chemical gradient structure. A second layer, enriched in chromium and/or silicon, is then deposited prior to surface aluminizing, which then generates the required gradient chemical structure.

**Figure 22** Micrographs of two SMARTCOAT structures: (a) SmC155, showing the three-layered structure characteristic of SMARTCOAT, but produced using air plasma spraying; (b) SmC253E, produced by occluded electroplating of the basecoat and chromium-rich interlayer.

**Figures 22(a) and 22(b)** illustrates two variants of this SMARTCOAT design. SmC155 (**Figure 22(a)**) is produced by surface-treating an Amdry 995 basecoat that has been deposited by air plasma spraying. The chromium-rich interlayer is also deposited by air plasma spraying before the bi-layer structure is aluminized to give the final SMARTCOAT design. The composition of the three-layered microstructure critically affects performance. The outer aluminide layer varies in composition between those of Ni–15Cr–32Al and Ni–10Cr–21Al, with small additions of Y as a result of the aluminizing of an MCrAlY base alloy, and is designed to produce a protective alumina scale for oxidation- and cyclic-oxidation-protection at temperatures above 900 °C. However, at lower temperatures, this alumina scale does not reform fast enough to confer a protection under type II hot corrosion conditions. SMARTCOAT is, therefore, designed with an intermediate chromium-rich layer, which permits the rapid formation of chromia, which are healing areas of type II corrosion damage. Research into optimum corrosion-resistant alloy compositions<sup>132,133</sup> defined the useful composition range of this interlayer, in the final chemical gradient structure, between Ni–60Cr–20Al and Ni–35Cr–40Al, adding tantalum may be beneficial. The basecoat may be any MCrAlY alloy, Amdry 995 (Co–32Ni–21Cr–8Al–0.5Y) for the SmC155 variant of SMARTCOAT.

**Figure 22(b)**, a second variant of SMARTCOAT, is produced using occluded electroplating<sup>134</sup> to deposit the basecoat and interlayer. Ghost images of the original particles in the occluded electroplate can still be seen. The base alloy is Amdry 963: a NiCrAlY

alloy; otherwise the coating procedure matches that of the aluminized, plasma-sprayed MCrAlY, but with the difference that the basecoat and interlayer were deposited by electroplating.

**Figure 23** illustrates the comparative performance of three variants of SMARTCOAT, when compared to two platinum aluminide coatings RT22 and CN91, and an over-aluminized CoNiCrAlY – a similar process and structure to that of GT29+, a General Electric proprietary coating. For each coating system, the substrate was IN738. The hot corrosion tests were of 500 h duration and conducted at 700 and 800 °C, using a salt recoat test procedure with daily replenishment of an 80% Na<sub>2</sub>SO<sub>4</sub>/20% K<sub>2</sub>SO<sub>4</sub> salt mix at an equivalent salt deposition flux of 0.015 mg cm<sup>–2</sup> h<sup>–1</sup>. The test was conducted in an air + 300 vpm SO<sub>2</sub>/SO<sub>3</sub> gaseous environment.

Under hot corrosion conditions, only the outer aluminide region of the smart coatings was attacked. The corrosion front effectively stopped at the chromium-rich interlayer, whereas the platinum aluminide coating was consumed down to the interdiffusion zone at 700 °C and completely penetrated at 800 °C. For the over-aluminized CoNiCrAlY, the worst attack was observed at 700 °C, as a result of severe type II pitting of the Co,Ni aluminide, and the underlying CoNiCrAlY basecoat layer.

#### 4.05.6 Summary and Conclusions

This chapter reviewed the methods and applications of diffusion coatings. Diffusion coatings can offer a

**Figure 23** Hot corrosion performance of SMARTCOAT SmC155 and SmC253E, relative to an over-aluminized CoNiCrAlY and platinum aluminide coatings (RT22 and CN91) at 700 °C.

low-cost solution for providing environmental protection, or can be a part manufacture of more sophisticated custom-designed coatings.

Applications may vary from aqueous corrosion protection through to high temperature oxidation and hot corrosion environments, and can encompass industries as diverse as aerospace, motor sports, petrochemical processes, chemical industries, steam turbines and advanced combined-cycle power generation plants.

Coating solutions vary from the low-cost aluminide diffusion coatings, first introduced into gas turbine service in 1957, through to platinum aluminide bondcoats for thermal barrier coatings.

To the future, one can foresee the development of 'custom surface engineering' solutions, where the component and coating are designed as a material system. SMARTCOAT is one such design for high temperature aggressive service condition, and there are many others. CVD and diffusion coating processes will form an important part of such functional surface engineering solutions.

### 4.06.1 Introduction

Hot-dipped coatings are prepared by cleaning a metal substrate, usually steel, and also other metals such as copper, and immersing it in a bath of molten (lower melting point) metal. During dipping, a reaction takes place to form a metallurgically bonded coating. The most widely used hot dip coating is zinc or alloys of zinc with other metals, followed by aluminum and tin

coatings. Typical thicknesses of hot dip zinc coatings on steel depend upon the application process. Pre-fabricated steel articles, such as structurals, dipped in zinc have coatings between 85 and 250- $\mu\text{m}$  thick, continuous galvanized sheet have between 10 and 20 $\mu\text{m}$  thick, and fasteners that are hot dip galvanized and then centrifuged have coatings around 50 $\mu\text{m}$  thick. Zinc–aluminum coatings are normally between 5 and 33 $\mu\text{m}$  thick. Aluminum–silicon coatings on

steel sheet are most often supplied between 6 and 33  $\mu\text{m}$  of thickness. The hot dip zinc coating not only serves as a protective barrier coating for iron and steel, with a generally much lower rate of corrosion than steel in the application environment, but is also electronegative to iron and protects it sacrificially.<sup>1</sup> Aluminum coatings also serve as barrier coatings, and provide sacrificial protection of steel in chloride-bearing environments. Tin coatings serve as barrier coatings, but are generally cathodic to steel in many environments and thus derive their utility from their corrosion resistance in selected application environments, such as food canning, together with other processability attributes.<sup>2</sup> The metallurgical reaction during hot dipping results in coatings that have two components: a reaction layer of intermetallic compound that is formed on the base of the steel, and an overlay of the molten coating bath that solidifies on top of this reaction layer and can be controlled to desired thicknesses during the hot dipping operation. The reaction layer thickness and character varies widely with the type of hot dip coating, for example, in the Zn–5% Al continuous galvanized coating, it is on the scale of nanometers, while after fabrication, galvanizing of reactive steels can give reaction layer thicknesses in excess of 60  $\mu\text{m}$ .<sup>3,4</sup> Both the overlay and reaction layers are important components in the ability of the hot dip coating to protect the substrate to which it is applied. Pure zinc is mostly used for general galvanizing, while zinc alloyed with about 0.2% aluminum is generally used for continuous galvanized sheet. In recent years, new alloy coatings have entered both sectors to improve either processability or corrosion resistance.<sup>5</sup>

In many cases, the hot dip coating is also given a surface treatment, either a chemical conversion layer such as chromate or an organic layer such as paint. A wide range of paints, meeting different demands for formability, weathering resistance, and appearance are available for galvanized steel. Aluminized steels are generally chromated but occasionally painted, while tin coatings can be lacquered if required.

## 4.06.2 Corrosion Characteristics of Zinc

### 4.06.2.1 General Considerations

Zinc coatings generally corrode as a result of the slow general dissolution of zinc from the surface. Zinc has the ability to form protective layers comprising basic carbonates, oxides, or hydrated sulfates, depending upon the nature of the environment. When protective

layers have formed and completely covered the surface of the coating, corrosion proceeds at a greatly reduced rate. Localized pitting occurs only under special conditions, for example, in waters where a calcareous scale may crack locally, exposing a small area of zinc. Provided that specifications are adhered to, intergranular corrosion of zinc is not a problem; however, certain impurities, especially in zinc aluminum alloy coatings, can cause intergranular corrosion. By its very nature, the protection of galvanized steel by zinc can result in bimetallic corrosion when steel surfaces are exposed, such as at cut edges, drilled holes, or when uncoated fasteners are inserted into structural items. Good design will minimize the amount of steel that is exposed to the environment and therefore minimize metallic corrosion.

The ability of zinc to maintain a protective layer is mainly determined by the pH of the environment, especially acidic pollutants. Because zinc forms an amphoteric oxide, strong alkalinity can also adversely effect zinc's corrosion behavior by interfering with the formation of protective layers. **Figure 1** shows that the corrosion rate of zinc varies with pH and shows that attack is most severe at pH values below 6 and above 12.5, while within this range, corrosion is

**Figure 1** Variation of corrosion rate with pH. Based on Noranda, *Designing zinc castings for corrosion resistance*; 1993; 24, and earlier data.

very slow. The actual rates of corrosion shown in this figure are not of direct relevance in any particular application, but mainly serve as a guide to the relative severity of corrosion.

Aluminum is particularly beneficial in zinc coatings and has resulted in development of trade name products such as Microzinc D4 (Zn->3%Al), Zinkopal (Zn-5% Al), Supergalva (Zn-5%Al), Galfan (Zn-5% Al), and Galvalume (Zn-55%Al). In these coatings with 5 and 55% aluminum, respectively, the surface is made up of mixed compounds of zinc and aluminum, which increase corrosion performance in many applications. **Figure 2** shows the effect of aluminum content on the corrosion resistance of Al-Zn coatings.

Zinc-iron alloys are present in a reactive layer formed on coatings prepared by dipping prefabricated steel in nearly pure zinc baths and also in the continuous galvanized sheet product termed 'galvanneal.' When coatings on prefabricated items are exposed for a sufficient time, the pure zinc overlay coating will be removed and expose the underlying zinc-iron reaction layer, causing a red staining. This is often confused with attack of the underlying steel; however, in many cases, this intermetallic layer, which contains in excess of 85% zinc, is capable of protecting the

underlying steel for many additional years. The galvanneal coating produced on continuous galvanized sheet is a fully alloyed coating with no zinc overlay. Its rough surface makes it particularly useful as a substrate for application of paints, while the ~85% zinc content of this intermetallic layer provides good protection to the steel substrate. Painted galvanneal has found widespread applications in automobile bodies and structures.

#### 4.06.2.2 Atmospheric Corrosion

Zinc and zinc alloy coatings have good resistance to atmospheric corrosion. Atmospheres are usually classified subjectively as industrial, urban, rural, or marine. In the first three classifications, the severity of corrosion is usually related to the amount of sulfur dioxide in the atmosphere, whereas in the latter the presence of chloride is an important determinant of corrosion rate. Guidelines for life expectancies of zinc coatings exposed to different atmospheres are shown in **Table 1**. The corrosion rate of zinc coatings is approximately linear with time in most aggressive atmospheres. Milder atmospheres allow the protective films formed on zinc to enable a decrease

**Figure 2** Five-year corrosion tests on early zinc-aluminum alloys; effect of aluminum content on corrosion performance of aluminum-zinc alloy coatings after exposure in various atmospheres: 1 mm = 25.4  $\mu\text{m}$ , 1 ft = ~0.035 m. Zoccola, J. C.; Townsend, H. E.; Borzillo, A. R. and Horton, J. B. In *Atmospheric Factors Affecting the Corrosion of Engineering Metals*, STP 646, Coburn, S. K. Ed.; American Society for Testing and Materials: Philadelphia, PA, 1978; pp 165-184.

**Table 1** Description of typical atmospheric environments related to the estimation of corrosivity categories and average corrosion rates for zinc

<i>Corrosivity category (C), Corrosion rate (based upon one year exposures), <math>r_{\text{corr}}</math> (m per annum), and corrosion level</i>	<i>Typical environments (examples)</i>	
	<i>Indoor</i>	<i>Outdoor</i>
C1 $r_{\text{corr}} \leq 0.1$ Very low	Heated spaces with low relative humidity and insignificant pollution, e.g., offices, schools, museums	Dry or cold zone, atmospheric environment with very low pollution and time of wetness, e.g., certain deserts, central Arctic/Antarctica
C2 $0.1 < r_{\text{corr}} \leq 0.7$ Low	Unheated spaces with varying temperature and relative humidity. Low frequency of condensation and low pollution, e.g., storage, sport halls	Temperate zone, atmospheric environment with low pollution ( $\text{SO}_2 < 5 \mu\text{g m}^{-3}$ ), e.g., rural areas, small towns. Dry or cold zone, atmospheric environment with short time of wetness, e.g., deserts, subarctic areas
C3 $0.7 < r_{\text{corr}} \leq 2$ Medium	Spaces with moderate frequency of condensation and moderate pollution from production process, e.g., food-processing plants, laundries, breweries, dairies	Temperate zone, atmospheric environment with medium pollution ( $\text{SO}_2$ : $5\text{--}30 \mu\text{g m}^{-3}$ ) or some effect of chlorides, e.g., urban areas, coastal areas with low deposition of chlorides, e.g., Subtropical and tropical zone, atmosphere with low pollution
C4 $2 < r_{\text{corr}} \leq 4$ High	Spaces with high frequency of condensation and high pollution from production process, e.g., industrial processing plants, swimming pools	Temperate zone, atmospheric environment with high pollution ( $\text{SO}_2$ : $30\text{--}90 \mu\text{g m}^{-3}$ ) or substantial effect of chlorides, e.g., polluted urban areas, industrial areas, coastal areas, without spray of salt water, exposure to strong effect of deicing salts, e.g., subtropical and tropical zone, atmosphere with medium pollution
C5 $4 < r_{\text{corr}} \leq 8$ Very high	Spaces with very high frequency of condensation and/or with high pollution from production process, e.g., mines, caverns for industrial purposes, unventilated sheds in subtropical and tropical zones	Temperate and subtropical zone, atmospheric environment with very high pollution ( $\text{SO}_2$ : $90\text{--}250 \mu\text{g m}^{-3}$ ) and/or important effect of chlorides, e.g., industrial areas, coastal areas, shelter positions at coastline
CX $8 < r_{\text{corr}} \leq 25$ Extreme	Spaces with almost permanent condensation or extensive periods of exposure to extreme humidity effects and/or with high pollution from production process, e.g., unventilated sheds in humid tropical zones with penetration of outdoor pollution including airborne chlorides and corrosion stimulating particulate matter	Subtropical and tropical zone (very high time of wetness), atmospheric environment with very high pollution $\text{SO}_2 (>250 \mu\text{g m}^{-3})$ including production and industrial zones and/or strong effect of chlorides, e.g. extreme industrial areas, coastal and off shore areas, occasionally contact with salt spray

Proposal for update to EN ISO 14713: 1999 incorporating corrosion rates for zinc set out in ISO 9223, UK Galvanizers Association, 2006.

in corrosion rate with time. Therefore, a straight line relationship will have a substantial safety margin in milder atmospheres. Corrosion rates increase as the amount of sulfur deposition in the atmosphere increases. Chlorides and nitrogen oxides usually are not as significant in determining corrosion resistance

as sulfur compounds, but, in combination with sulfur, can significantly increase corrosion rates. Corrosion resistance also increases with time of wetness. Therefore, the relative humidity and the amount of rainfall both influence the observed corrosion rate. [Table 2](#) gives the results from the ISOCORRAG

tests for a 3-year period in many locations around the world.<sup>6</sup> The ISOCORRAG severity classification is given. The steel/zinc ratio is shown for both flat and helical-shaped samples together with environmental characteristics that govern atmospheric corrosion.

#### 4.06.2.3 Water Corrosion

Zinc coatings provide good protection for steel in hard waters, where the scale forming ability of the hardness salts allow for development of passive layers. Less favorable corrosion resistance is seen in distilled and soft waters. Zinc, being an amphoteric metal, exhibits good corrosion resistance in water having a pH near neutral. The corrosion rates of both galvanized and aluminized steels in four potable waters in the Soviet Union are shown in Table 3. The normal application of galvanized steel with potable water is in the form of supply pipes.

Seawater corrosion of galvanized steel is moderate in temperate climates, but more severe in the tropics. In temperate seawater, magnesium salts are sufficient to act as inhibitors. Typical corrosion rates are 25  $\mu\text{m year}^{-1}$  in the tropics and half that in the temperate seas such as the North Atlantic. In tidal areas, in which twice daily immersion occurs, or in areas splashed by waves, the corrosion rate is typically twice as great as that for completely immersed areas.

#### 4.06.2.4 Soil Corrosion

There is a wide variation and composition of natural soils, and therefore, a wide range of corrosion rates that can be expected from galvanized steel, but sandy,

well aerated soils with neutral or slightly alkaline pH are likely to cause only limited corrosion of zinc-coated steel. Zinc coatings prevent pitting of steel in soil, and even when the zinc coating is destroyed, the coated steel corrodes much less than do the bare specimens. The controlled use of backfilled materials can allow for satisfactory use of zinc-coated steel in soil contact applications. Typical corrosion rates of galvanized steel pipe in contact with a variety of soils in the United States are shown in Table 4. Here, it is indicated that inorganic oxidizing soils should allow an 85  $\mu\text{m}$  coating to provide at least 10 years of protection. In most inorganic reducing soils, a 130- $\mu\text{m}$  coating should give 10 years of life; however, this thickness would not be sufficient to protect steel in soils containing highly reducing organic or inorganic matter, or in cinders.<sup>7</sup>

#### 4.06.2.5 Other Corrosion Media

Alkaline solutions of ordinary laundry soaps develop a protective coating when in contact with zinc coatings. Satisfactory corrosion rates are observed with both warm and cold applications. Detergent solutions are more corrosive; however, the better grades include inhibitors that reduce corrosion and allow the use of zinc-coated containers. Strong alkalis will result in excessive corrosion.

Many inorganic chemicals may be used in contact with zinc; however, in the presence of moisture, or with water in solution, many inorganic chemicals react with zinc. Mixtures of chemicals can sometimes be more corrosive than the sum of their separate effects, but in many cases, there are often inhibitors present that

Normal mass coating,  $915 \text{ g m}^{-2}$  of exposed area, is the mass of coating on one side of the pipe;  $915 \text{ g m}^{-2}$  is equivalent to approximately 0.13 mm thickness of coating.

Source: Romanoff, M. *Underground Corrosion*; National Association of Corrosion Engineers (NACE): Houston, TX, 1989. (Originally Issued by the National Bureau of Standards, Circular 579, 1957).

give a net beneficial effect. A short immersion trial is desired for water-based solutions, from which results can be linearly extrapolated to give the worse possibility, because attack often reduces with time.

Many organic chemicals can be used with zinc-coated steel, and many of these organic liquids are inert in contact with zinc. Air entrapped during encapsulation and vapor from polymeric materials such as epoxy resin can cause corrosion. When 85–90% humidity is present, zinc can deteriorate in contact with several synthetic organic chemicals.

Zinc-coated steel is not highly corroded when it is placed in contact with pure fuels, but sulfur or water in ordinary fuels may form compounds with zinc that can both cause high corrosion rates and also form compounds that can clog small orifices. Surface treatments that provide resistance to sulfur or moisture impurities are recommended in this application.

Many lubricants, when in contact with galvanized steel, produce a smooth lightly etched surface, and therefore, form a natural protective coating. Lubricants should be stable and free from acidity. Lubricants

of mineral origin are completely satisfactory, while those containing animal or vegetable oils or fats should be avoided.

Chromated zinc coatings are widely used in contact with concrete in reinforced concrete applications. Galvanized reinforcing bar in concrete has a much higher tolerance for chloride contamination of the concrete resulting from marine exposure or contact with deicing salts. Zinc corrosion products are much less expansive than are iron corrosion products, greatly reducing the risk of cracking, rust staining, and spalling of concrete. Static strength and bond strength of the reinforcement in concrete is not affected by the presence of the coating.

One form of general corrosion that is not protective is 'white rust,' more properly called wet storage stain. This corrosion occurs when there is access for water but limited supply of oxygen and carbon dioxide. The presence of chlorides and sulfates accelerates wet storage stain formation. White rust is particularly found in newly galvanized, bright surfaces, and especially in crevices between closely

packed galvanized articles. In such cases, the surfaces come into contact with moisture, and it cannot dry quickly. Zinc surfaces that already have a normal protective layer of corrosion products are seldom attacked. The presence of white rust does not affect the functional corrosion resistance of the zinc coating. Short-term protection against white rust is attained by chromating or phosphating. Freshly galvanized work should always be stored, so that all surfaces are well ventilated and water allowed to easily run off the surfaces.

### 4.06.3 Corrosion Characteristics of Aluminum

Low corrosion rates are seen with aluminum-coated steel between pH levels of 5 and 8.5. Like zinc, aluminum is amphoteric and its corrosion dependence on pH of several media is shown in **Figure 3**. Aluminum corrodes under both acidic and alkaline conditions; however, when the corrosive environment is highly oxidizing, the aluminum oxide film will be more protective. Also, in several specific cases, the oxide film is not soluble in acidic or alkaline solutions. Two notable examples are acetic acid and sodium disilicate, which are shown in **Figure 3**. Ammonium hydroxide with >30% concentration by weight, nitric acid at >80% weight concentration, and sulfuric acid of 98–100% concentration are also exceptions. There is no general relationship between pH level and the rate of attack, because specific ions largely regulate corrosive behavior. Aluminum coatings are inert to strong nitric or acetic acid solutions, but are easily attacked in dilute nitric, sulfuric, or

hydrochloric acid solutions. Similarly, solutions with a pH as high as 11.7 may not attack aluminum alloys, provided silicate inhibitors are present, but in the absence of silicates, appreciable attack may occur at pH levels as low as 9.0. Generally, less corrosion occurs in the near-neutral pH range of chloride-containing solutions, 5.5–8.5, than in more distinctly acid or alkaline solutions.

Aluminum coatings are not appreciably corroded by distilled water even at temperatures up to 180°C. For this reason, aluminum-coated steel can be used in many distilled water storage and handling applications, provided the coating is continuous, so that the underlying steel is not exposed. Freshwaters vary widely in their composition, and in many cases, the use of aluminum-coated steel in contact with many freshwaters will be satisfactory. However, certain waters may cause severe localized attack or pitting. Pitting is of special importance when coatings are thin. However, aluminized culvert is widely used for freshwater drainage applications. In this case, the greater hardness of aluminized coatings provides better abrasion resistance compared with zinc, even though the aluminized coating provides only barrier, and not sacrificial protection of the steel.

Corrosion of aluminum coatings in seawater is mainly characterized by pitting. Rates of pitting usually range from 3 to 6  $\mu\text{m year}^{-1}$  during the first year and from 0.8 to 1.5  $\mu\text{m year}^{-1}$  after that.

### 4.06.4 Corrosion Characteristics of Tin

As with other metal coatings, the corrosion rate of tin in the atmosphere is highly influenced by moisture. In dry conditions, slow growth of tin oxide is expected; however, in wet conditions, tin coatings behave in a manner similar to that of steel. In wet conditions, tin behaves as a cathode for steel, being more noble than steel in the electromotive series. The only barrier offered by tin to steel under such conditions is as a physical barrier.<sup>2</sup>

Liquid phase corrosion of tin has been extensively studied because of the use of tin steel in food-containment applications. However, the necessary control of process temperatures and times of cooling to ensure product safety, usually results in the avoidance of tin corrosion problems. However, poor drying of cans may initiate corrosion that is only observed later. Also, poor practice regarding external

**Figure 3** Relation to pH of the corrosivities towards 1100-H14 alloy sheet of various chemical solutions. Revie, W. R. *Uhlig's Corrosion Handbook*, 2nd ed.; Wiley, 2000; Chapter 40, pp 677–714.

packaging, such as shrink wrapping of wet cans may trap water and cause noticeable tin corrosion. Uptake of chloride from cardboard in contact with food cans may also cause local attack.

Within tin cans, the corrosion of tin is largely affected by the character of the contained food or other substances such as beverages, domestic cleaners, paints, and decorative materials, together with a wide variety of other materials that are stored or transported in tin cans. Organic complexes such as citrate or tartrates can result in conditions that influence the nature of tin corrosion. Pesticide residues or the residues from nitrate fertilizers may also be present. Some foods and beverages are themselves likely to attack steel. Thus, cola-type drinks having phosphate as well as citrate ions and low pH tend to be iron dissolvers. As these products are normally packed in lacquered cans, the potential effects of a large tin cathode are minimized and hence perforation is uncommon. Tinned meats, fish, and vegetables (such as peas) can contain sulfur-bonded protein species. During processing, these may breakdown to yield hydrogen sulfide, which can react readily with both tin and steel. Although they offer no food contamination problems because of the low solubility, they are unsightly. This can be controlled by using internal lacquers pigmented with zinc carbonate or oxide. The sulfide reacts with these pigments, but the resulting zinc compound is off-white and causes no concern to the customer.

#### **4.06.5 Applying Coatings by Hot Dipping**

##### **4.06.5.1 Introduction**

Dipping of metals into molten lower melting point metals is the oldest, simplest, and generally, the cheapest method of forming a surface coating. The base metal must withstand the dipping temperature without undesirable changes in properties. To obtain a coating, the coating metal must be wetted and alloyed with the substrate. The coating metal, in addition to having a lower melting point, must be inexpensive and must confer the desired properties: corrosion resistance is the most important, but often the coated product is required to be formed and must have reasonable abrasion resistance. Commercial coating of zinc, aluminum, tin, and their alloys are most important. Steel is by far the most important metal that is coated by hot dipping. Cast irons are also coated by hot dipping and some copper is coated with tin or tin alloys. Stainless steel is hot dip

coated with aluminum, mainly for use in automotive exhaust systems. Other hot dip coatings are only applied for special purposes.

The dipping processes are of three basic types: (1) continuous lengths of strip, wire, or tube pass through the molten coating metal; (2) semimanufactured products (such as cut tube lengths or sheets) are dipped into the molten metal in batches in specially designed and automatically operated plants; and (3) fabricated products are dipped into the molten metal.

The coatings produced are designed to differ because with most semifabricated materials, such as sheet, the final coating needs to be formed as easily as the base metal, whereas on fabricated products this does not apply and thicker coatings with better corrosion resistance are provided. The vast majority of coatings are zinc based: more than 20 times as much zinc is used for hot dip coatings as the total of all other hot dip metallic coatings. All three types of processes apply for hot dip zinc (galvanizing) and zinc–5% aluminum coatings. Hot dip aluminum coatings (aluminizing), while used in the past on fabricated products, are now expanding for continuously coated strip and also for wire. The 55% aluminum–43.5% zinc–1.5% silicon coating (Galvalume type) and Zn–Al–Mg coatings are used similarly for continuous coating of strips where the coating operation can be in a controlled atmosphere. Hot tinning is used to protect food containers and also to facilitate the soldering of steel, copper, brass, and other metals, for example, copper wire is often tinned. With continuously coated steel sheet and wire, in addition to thin coatings, the ‘terne’ coating, an alloy of lead usually with 2–25% tin, continues in industrial use as a coating for steel sheet and wire, although because of environmental concerns, it has largely been replaced by lead-free materials.

##### **4.06.5.2 Principles of the Hot Dipping Operation**

Most of the principles of hot dipping are common to galvanizing, tinning, terne coating, and aluminizing.

###### **4.06.5.2.1 Cleaning**

The surface must be cleaned of oil, grease, and other surface contaminants and also scale and oxide, using degreasing and/or pickling treatments as required. The original Sendzimir pretreatment of steel strip by oxidation followed by reduction at high temperature or other high temperature gaseous treatments, developed more recently, eliminates the necessity for

these operations and also for fluxing, although electrolytic cleaning can be used before the gaseous treatment processes, to obtain the highest quality hot dip coatings on strip.

Keeping the material in a controlled atmosphere is often sufficient to retain a clean surface until coating takes place, but where exposure to air occurs (as with most coating of fabricated articles), a flux coating is usually applied to keep the surface clean and free from oxide. Fluxing may be by immersion in an aqueous prefluxing bath, followed by drying, or by passing through the molten flux floating on the bath of molten metal, or both of these. Molten flux attacks the surface, cleaning it and promoting the wetting of the base metal by the molten metal in which it is dipped.

#### 4.06.5.2.2 Dipping

Strip or wire is coated continuously, up to  $4 \text{ m s}^{-1}$  in speed. Continuous coating plants in which the sheet is continuously uncoiled, passed through the coating equipment, and then recoiled have largely replaced cut sheet plants, except in developing countries. Fabricated articles are either dipped in batches, mounted on suitable jigs if small, or singly if large, and the operation may be mechanized. Small articles and threaded work are dipped in perforated baskets suitable for subsequent centrifuging before the coating solidifies. Assuming that the articles to be coated have been properly cleaned and fluxed, the base metal and the molten coating metal interact on dipping, producing an alloy layer. If the article is colder on entry than the melting point of the coating metal, there may be a short intermediate stage where a solid skin forms around the article. Frequently, the base metal (or article) is preheated to avoid this.

For any given pair of metals, the total amount of alloy increases with the duration of immersion and is also affected by the temperature of the bath.

The amount and nature of the alloy layer may also be profoundly affected by additions to the molten bath, such as silicon to an aluminum bath or aluminum to a galvanizing bath. The change in the composition of the base metal may also have a marked effect, for example, mild steel containing a little silicon continues to react with zinc at a steady state throughout immersion, whereas with steel without silicon, the reaction rate decreases with time. Although the alloy layer is always referred to as if it were a single layer, it is usually made up of two or more layers, corresponding to known metallurgical phases. Reaction can occur after the work has left the molten metal bath while the coating is solidifying and cooling.

#### 4.06.5.2.3 After treatments

These include processes intended to produce one or more of the following results:

- Reduction of coating thickness by reducing the amount of molten metal adhering to a substrate as it leaves the bath. Air or gaseous jets are used for control of the coating thickness of continuous sheet and wire and tubes. For fabricated articles, this is done by centrifuging while the coating is still molten.
- Improvement of the properties or appearance of the coating for substrates. Such improvements include quenching (to avoid unwanted alloy growth), chromating and phosphating, and special treatments in both chemical and mechanical types for sheet such as temper rolling and stretch leveling.
- Change in the character of the coating – as distinct from the more superficial treatments listed under (b). Hot-dipped zinc coatings are sometimes annealed to convert the whole of the coating into alloy as are aluminum coatings intended for heat resistance.

### 4.06.6 Hot Dip Galvanizing

#### 4.06.6.1 Introduction

Large tonnages of fabricated steelwork are hot dip galvanized each year. Over 6 million tons of steel were hot dip galvanized within the European Union in 2006.<sup>8</sup> The principles of hot dip galvanizing have remained unchanged for 150 years; however, a vast amount of research has enabled the industry to become technically advanced over this period. Many changes to plant configuration have also been brought about in response to modern national and European environmental and health and safety legislation. The hot dip galvanizing process essentially consists of cleaning the articles (degreasing and pickling), fluxing the work, and then immersing the work in a bath of molten zinc. Coated work can then be either quenched or allowed to air cool.

#### 4.06.6.2 Design for Hot Dip Galvanizing

Steelwork intended for processing should ideally be designed with the coating process in mind.<sup>9</sup> When an article is received for hot dip galvanizing it is assessed for suitability for further processing. It should be free from contamination, which would not be removed in

the normal pretreatment process prior to galvanizing. It is important that the design allows adequate handling through the process and for the access and egress of all pretreatment solutions and molten zinc. Articles containing sealed volumes should not be hot dip galvanized, because any residual water or other solutions contained within the void will evaporate and are likely to generate sufficient pressure to cause an explosion – ejecting molten zinc from the galvanizing bath and compromising operator safety. Distortion can occur in some fabrications because of relief of unbalanced steel production stresses and or fabrication stresses in combination with the thermal stresses brought about during dipping. Articles destined for galvanizing, having been fabricated from elements with very dissimilar geometries (thickness), utilizing high-strength steels, and particularly those adopting designs that incorporate highly restrained joints, can in specific circumstances become more susceptible to steel cracking during galvanizing by one or more mechanisms (strain-age embrittlement, hydrogen embrittlement, or liquid metal assisted cracking), and guidance exists to manage these risks.<sup>10,11</sup>

#### 4.06.6.3 Degreasing and Pickling

Steelwork is commonly degreased in acid or alkaline solutions prior to rinsing in cold water. The work is then pickled in either a sulfuric acid solution or a hydrochloric acid solution. Sulfuric acid is usually operated at a strength of around 14% and at a temperature of 60–80°C, whereas hydrochloric acid would normally be operated across a range of ~5–14% and at ambient temperatures.<sup>12</sup> Inhibitors are added to the acid to reduce potential for overpickling on clean areas of steelwork. Rather than operate a separate process tank, acidic degreasers can also be added to a pickle tank obviating the need for a separate degreasing stage. Pickling will be followed by another water rinse stage.

Grit blasting is often used to remove tenacious contamination on castings, to remove welding slag from fabricated steelwork, or in specific instances where a rougher steel surface profile is required in order to attract development of a thicker galvanized coating. Where grit blasting is carried out, the work is normally ‘flash pickled’ to remove any residual loose contamination prior to further processing. Hydrofluoric and mixed acids can also be used to pickle castings, but these are extremely dangerous chemicals and great care is needed when working with these agents.

#### 4.06.6.4 Fluxing

After degreasing and pickling, work is fluxed to prevent further oxidation of the surface and to aid wetting of the surface when it comes into contact with the molten zinc. Fluxing has historically taken place in a variety of ways – ‘old dry,’ ‘dry,’ and ‘wet’ methods **Figure 4**. The ‘dry’ method dominates for general galvanizing, while the ‘wet’ method is still used when processing smaller articles in spin-galvanizing operations for instance.

The ‘old dry’ method consists of drying the work after pickling and allowing the dried on salts to provide the fluxing action prior to dipping in the molten zinc. The ‘dry’ method involves dipping the pickled and rinsed work into a flux solution and afterwards drying the work in a pit or oven prior to dipping the work into the molten zinc. The ‘wet’ method involves passing the pickled and rinsed work through a blanket of flux floating on the top of the zinc melt.

Where the ‘dry’ process of prefluxing is used, the solutions adopted are usually based upon zinc ammonium chloride (a common form being the double salt  $\text{ZnCl}_2 \cdot 3\text{NH}_4\text{Cl}$ ). Operating strength is usually up to 30% and operating temperatures of up to 80°C can

**Figure 4** Flow diagram showing handling operations in the galvanizing process. *General Galvanizing Practice*; Galvanizers Association: UK; 1999; p 3.12.

be used. Other fluxes, which include a proportion of sodium chloride or potassium chloride, can also be used. These fluxes, while requiring more care for optimum operation, have been reported to produce fewer fumes during dipping of the work than do the traditional zinc ammonium chloride solutions.<sup>13,14</sup>

When drying the work prior to dipping in the molten zinc, care is needed to ensure that the flux on the work is not degraded by overheating. Normally, article surface temperatures are limited to 150°C maximum. The time between fluxing and dipping in the molten zinc should be minimized to maintain the effectiveness of the flux.

#### 4.06.6.5 Galvanizing

Upon immersion of the prepared article into the molten zinc a series of iron–zinc intermetallic compounds are formed on the surface of the article (gamma ( $\Gamma$ ), delta ( $\delta$ ), zeta ( $\zeta$ )). Upon withdrawal of the article from the galvanizing bath, a proportion of molten zinc is also withdrawn on the work (forming the eta ( $\eta$ ) layer). This solidifies as the work cools (see **Figure 5**).

‘Spin-galvanizing’ or ‘centrifuge galvanizing’ is a variation of the general galvanizing process where articles are contained within a perforated basket during pretreatment and dipping in the zinc melt. After withdrawal, the basket is placed in a container, which spins the work to remove a proportion of the free (semimolten) zinc from the coating. This type of process is often used for small articles such as fasteners and washers. The spinning process produces a thinner coating than that of the general galvanizing process, a factor that is reflected in the standards and specifications associated with products processed in this way.<sup>15</sup>

##### 4.06.6.5.1 Coating development and reactivity of steel

Conventional operating temperatures for galvanizing are between 445 and 465°C. High temperature galvanizing is carried out between 530 and 560°C. Galvanizing processes are not operated at temperatures between these two ranges.<sup>16</sup> Operators of the higher temperature process use ceramic galvanizing baths to overcome problem of the increased reaction rate between steel and zinc at these high temperatures. For silicon-free steel, the reaction rate between iron and zinc is parabolic with time in the temperature range 420–490°C (the lower parabolic range). At temperatures between 490 and 510°C, the reaction rate is approximately linear with time (known as the linear region). The reaction rate reverts to a parabolic relationship at temperatures above 530°C (the upper parabolic region).

The thickness of the alloy layers within the coating formed on a steel article will depend principally on (a) the chemistry of the surface of the steel, (b) the surface roughness of the steel, (c) the temperature of the galvanizing bath, (d) the time of immersion, and (e) the rate of cooling.<sup>17</sup>

The role of silicon and phosphorus in development of alloy layers in a galvanized coating has been subject to intense research over many years.<sup>18,19</sup>

Silicon-killed steels, containing Si over 0.3%, produce a thick gray galvanized coating on processing. These thick gray coatings consist predominantly of all zinc–iron alloy (see **Figure 6**). While offering extended periods of corrosion protection, they are often less resistant to mechanical damage. Steels containing between 0.15% and 0.25% Si often produce

**Figure 5** Structure of a galvanized coating on a normal (un killed) steel. *The Engineers and Architects' Guide: Hot Dip Galvanizing*; UK Galvanizers Association Publication, 1999.

**Figure 6** Structure of a galvanized coating on a reactive (silicon-killed) steel. *The Engineers and Architects' Guide: Hot Dip Galvanizing*; UK Galvanizers Association Publication, 1999).

coatings that retain a proportion of zinc on top of the zinc–iron alloy layers.

Where semikilled steels are processed, the results are less predictable. Steels containing between 0.04% and 0.14% Si often produce coatings that are very thick and exhibit poor cohesion. This reactivity range (see [Figure 7](#)) is often known as the ‘Sandelin peak,’ named after the researcher who described the effect some years ago.<sup>20</sup> Phosphorous is more influential in determining coating characteristics at these lower silicon concentrations. The International Lead Zinc Research Organization (ILZRO) has set out a classification system for reactivity of steels, which is broadly in line with the Sandelin data.<sup>21</sup> Hot dip galvanizing of reactive steels is often associated with increased zinc usage.

The effect of silicon can be suppressed by galvanizing at higher temperatures (530–560°C). High temperature galvanizing is often (but not exclusively) used to process small work also, adopting the ‘centrifuge’ or ‘spinning’ process.<sup>15</sup>

Alloy layers tend toward increased thickness on rougher steel surfaces, and because of the increased surface area, they are able to take part in the reaction between the zinc and the iron.<sup>22</sup> In practice, a maximum uplift in coating of ~50% can be achieved for steel that has been grit blasted prior to galvanizing compared with the coating developed on a steel of similar thickness and surface chemistry that has not been subject to blasting.

The alloy layers grow more rapidly as temperature increases – but there are practical limits to the extent to which this factor can be used to control alloy layer growth.<sup>23</sup>

Coating development normally tends to follow a parabolic reaction rate when articles are first immersed in the zinc melt. Very reactive steels

**Figure 7** Illustration of the ‘Sandelin’ curve – Hot dip galvanized coating development with increasing steel surface silicon concentration. *General Galvanizing Practice*; Galvanizers Association: UK; 1999; 1.8.

(particularly those with high (>0.25%) or critical levels (0.04–0.14%) of silicon and phosphorus) exhibit a reaction rate for coating growth that is more linear with time (see [Figure 8](#)).

The alloy layer may continue to grow slowly during the cooling of the work after galvanizing. This is rarely an important consideration except when very heavy sections are being processed. In extreme cases, the alloy layer diffuses to the surface to form grey patches. This is often referred to as a ‘gray coating’ or ‘gray bar.’<sup>24</sup>

#### 4.06.6.5.2 Alloying additions the zinc melt

Alloying additions to the galvanizing zinc melt can be made to control the rate of coating development for reactive steels. Depending upon the specific alloying element(s) being introduced to the galvanizing zinc

**Figure 8** Illustration of galvanized coating development with time for normal (unkilled) and reactive (silicon-killed) steel. *General Galvanizing Practice*; Galvanizers Association: UK, 1999; 1.8.

melt, these additions can be made directly or in the form of a master-alloy.

Most galvanizing melts will contain ~98.5% zinc. Lead will be found in zinc melts produced by melting zinc stock originating from a thermal production route (e.g., imperial smelting process). Although the solubility of lead in zinc is ~1.4% at 450°C, common concentrations of lead in zinc melts will run up to ~1%. Lead assists wetting of the steel surface and reduces the surface tension of zinc, thereby encouraging greater fluidity and better drainage from the article.<sup>25,26</sup>

Nickel additions to the zinc melt of ~0.05–0.06% have been found to be most effective for controlling coating development on steels that exhibit silicon concentrations up to 0.2%, effectively eliminating the development of reactive coatings in this range.<sup>27,28</sup> The effects of bismuth on the zinc–nickel-based melt have also been studied.<sup>29</sup>

Historically, aluminum additions of up to 0.005% have been used to aid brightening of the work and reduce the rate of oxidation of the zinc.<sup>30,31</sup> Galvanizing melts commonly operate using aluminum levels of ~0.001–0.002%.

Tin additions to the zinc melt at concentrations up to around 2% had been found to be effective in controlling steel reactivity across the range of common silicon concentrations in steels and providing coatings with bright finishes.<sup>32,33</sup> Although the role of tin during galvanizing for concentrations up to 5.0% have also been investigated,<sup>34</sup> tin levels of ~0.3%, particularly when used in combination with bismuth (around 0.1% maximum to improve melt fluidity), have found wider currency in Europe for controlling steel reactivity. Zinc alloy melts using total for tin, bismuth, and aluminum (total Sn/Bi/Al < 1%) have also been developed, which provide a smooth, bright, spangled finish to the galvanized coating.<sup>35</sup> The additions of tin to the melt allow for operation of higher aluminum levels without detriment to coating continuity (development of bare spots).

Use of other alloying additions (alone or in combinations), such as vanadium,<sup>36,37</sup> manganese, and titanium,<sup>38</sup> have also been investigated to either control steel reactivity or develop a more consistent coating thickness, texture, or appearance while maximizing profitability and minimizing production of waste streams.

Almost from 2002, zinc–5% aluminum coatings have also been developed for application through the general galvanizing process, albeit on a more limited scale than coatings developed through conventional zinc melts (zinc concentration 98.5% minimum).<sup>39</sup> Coatings of Zn–23% Al have also been investigated.<sup>40</sup>

#### 4.06.6.6 Post-Galvanizing Treatments

Work which has been galvanized is often either left to air-cool or quenched in water. The quench water may contain a passivation treatment (chromate or phosphate), which retards the early onset of wet storage staining during transport or storage.<sup>41</sup> Quenching the work has the advantage of removing potential flux residues that might stain the work and allowing more rapid cooling of the work, thereby reducing the potential for development of all alloy layered coatings on components fabricated from reactive steels. The work will also be cooler to handle, allowing earlier movement of work away from the processing area.

#### 4.06.7 Continuous Zinc and Zinc Alloy Coating

Large tonnages of wire and sheet are galvanized on automated lines by continuously uncoiling the steel,

passing it through the coating line, and recoiling it. In the past 20 years, development of techniques for coating steel sheet with zinc and zinc alloys, and pretreating advanced high-strength steels now demanded by automakers, have been the major advances.<sup>42</sup>

Surface pretreatment is now principally by gaseous treatments in most strip lines and some wire lines; pickling remains for other products. In the gaseous pretreatment processes, steel is fed into the galvanizing bath through a snout, which dips below the surface of the molten zinc and protects the surface against reoxidation. This eliminates the need for fluxing. The strip enters the molten zinc at a temperature of 470–480°C; most of the heat required for the galvanizing bath is supplied by the sheet itself.

Chemical cleaning and fluxing (wheeling process) without gaseous treatment also has limited use, mainly for building panels and other sheets in which economical development of high tensile strengths is desired. External coating of small diameter tubes in which zinc is pumped over the steel instead of the steel being dipped uses either an inert atmosphere or a flux pretreatment.

Painting of galvanized sheet best involves no-spangle or minimum spangle galvanized surfaces that provide good specular reflectivity without the substrate surface structure being visible. The traditional spangled galvanized surface is now only rarely seen on sheet intended for painting. Spangle reduction is achieved by sweeping the coating with narrow jets of steam or air or by depositing a large number of crystallization nuclei on the surface just before solidification. A skin pass, with a reduction of <1%, after solidification is an alternative method. Paintability (and weldability) is also improved by converting the surface to a zinc-iron alloy (galvannealing) in line.

Steel wire is also galvanized on a continuous basis and the principles of the Sendzimir sheet galvanizing process and later developments have been applied as an alternative to wet cleaning and pickling. Certain grades of wire that require tensile strength may require redrawing of the wire after coating.

For annealed wire, the strands of wire are first taken through a bath of molten lead, where the desired softening and a partial cleaning effect, termed patenting, is achieved. Strands are then pickled, fluxed, and galvanized. Wiping of the wire after galvanizing controls coating thickness. Wires with heavier coatings are drawn through a bed of charcoal, while for thinner coatings, wiper pads are held against the wire by various means. At higher line speeds, gas wiping is practised.

#### 4.06.8 Hot Tinning

Like zinc coatings, hot dip tin coatings possess an intermetallic coating covered with the solidified metallic coating. Cleaning and pickling treatments for prefabricated article are similar to hot dip galvanizing. The aqueous flux solution is also similar to galvanizing solution, consisting typically of 240 g l<sup>-1</sup> of zinc chloride, 60 g l<sup>-1</sup> of sodium chloride, 30 g l<sup>-1</sup> of ammonium chloride, and 6–12 ml l<sup>-1</sup> of hydrochloric acid (sp. gr. 1.14). Articles, wet with flux solution, are lowered into a bath of molten tin at about 280°C, having a layer of fused flux floating on it, covering about two-thirds of its surface. The flux cover is composed of a mixture of dry chlorides in the same proportions by weight, as the flux solution being carried over with the work. After the article reaches the temperature of the tinning bath, flux is removed from the immediate surface of the bath and the article is immediately withdrawn through the flux free area of the tin surface. Coating quality may be improved by redipping in a second tinning pot where the tin is covered with a layer of molten grease such as tallow at a temperature of 240–270°C. Small articles may be tinned in batches using jigs or baskets and then spun in a heated centrifuge to remove excess tin. The brightness of the tin coating may be preserved by quenching the articles in a layer of paraffin or kerosene, 50–100-mm thick, floating on water. Small parts can be separated from one another before the tin coating solidifies by allowing them to fall on a paddle wheel rotating at 500–1000 rpm. For strip, pretreatment uses electrolytic alkaline degreasing followed by electrolytic pickling. Work then passes downward through a layer of molten zinc chloride flux into the molten tin at 300–320°C on emerging sheet passed through pressure rolls and palm oil at 240°C to remove tin. A hot dip tin coating on a steel layer has a layer of FeSn<sub>2</sub> at the interface between the tin and the steel. This alloy grows very slowly in comparison with the more complex alloy layers formed in galvanizing and then aluminizing. It usually comprises 10–20% of the total coating thickness. Tin-lead coatings containing two or more percent of tin may be applied by hot dip processes to steel, copper, and copper alloys. Steel sheets are commonly coated with alloys containing 7%, 10%, or 25% tin. These are called terne plate with the name tin-terne, sometimes applied to the higher tin coating. Coating quality can be improved by electroplating the steel substrate with nickel before hot dipping in the terne bath.

### 4.06.9 Hot Dip Aluminizing

Fabricated articles are less commonly hot dip aluminized now, than in the past. Coatings are applied after cleaning the work, including degreasing, pickling in hydrochloric acid, and then preheating. The work is then immersed in a molten salt bath, a flux or reducing atmosphere, prior to immersion in the bath of molten aluminum. Alloying occurs between iron and aluminum at the interface.

Type I aluminized steel strip (used in high temperature conditions) is coated with aluminum–silicon alloy containing typically 5–11% silicon, whereas the Type II grade (for corrosion prevention) is coated with a heavier layer of ‘pure’ aluminum, although heavier aluminum–silicon coatings are also referred to as ‘Type II’. A disadvantage of silicon-containing aluminum coatings is that they darken when subjected to atmospheric corrosion; Type I grade of aluminized steel possesses total coating thicknesses, including the alloy layer, between 14 and 25  $\mu\text{m}$  (80–150  $\text{g m}^{-2}$  including both sides) whereas Type II grade has in excess of 40  $\mu\text{m}$  (230  $\text{g m}^{-2}$  including both sides). In both cases, about 2–4% of iron is present in the coating alloy. This is iron dissolved from the strip and the coating bath hardware. An alloy layer containing intermetallic compounds can be seen between the coating layer and the steel substrate in both grades. This layer is thicker in the Type II grade. As intermetallic compounds are generally very brittle, it is desirable to keep the alloy layer fairly thin. Silicon additions help control the thickness of the alloy layer. In both grades, it thickens with time and temperature, at a rate that is generally parabolic, but there is a slower rate of thickening of the alloy layer in the Type I grade, likely because of a combination of a higher dissolution rate and a slower solid state growth rate.

Post annealing, an overageing heat treatment carried out for an hour at 400–500°C, can slightly increase ductility. A coating which has a total thickness of 25  $\mu\text{m}$  in which the alloy layer occupies about 25% of the total has satisfactory bending properties. Excessive deformation causes cracking of the alloy layer or delamination of the coating. The thicker alloy layer in the Type II grade tends to crack more readily than that on Type I.

Aluminized steel has far better heat resistance than do galvanized steel, maintaining a bright metallic surface on exposure to temperatures up to ~500°C. Higher temperatures will lead to the conversion of any free aluminum at the surface to iron aluminum

compounds. Exposure to temperatures up to 700°C are possible without promoting breakdown of the steel substrate. Aluminized steel does not suffer from the intergranular embrittlement problems arising from intergranular diffusion of zinc reported for galvanized steel at high temperatures. Galvalume, a strip product coated with an alloy containing 55% Al–43.5% Zn–1.5% Si, has also been reported to suffer from intergranular embrittlement at temperatures close to 500°C, although this can be prevented by increasing the phosphorus content of the substrate steel above 0.04%.

### 4.06.10 Hot Dip Coatings with Applied Organics: Duplex Systems

Hot dip galvanized coatings by themselves provide a long lasting and cost-effective means of corrosion protection for iron and steel articles in most applications. When organic systems are applied on top of the galvanized article, this becomes known as a duplex coating. Duplex coatings are often used to add color for aesthetic reasons (camouflage or contrast), to increase the economic life of the structure by providing additional corrosion protection, or to provide greater protection in aggressive corrosive environments.

Organic systems used in conjunction with galvanized coatings often provide a life for a structure, which are longer than the sum of the lives of the coatings used independently.<sup>43</sup> EN ISO 12944 provides information on preparation of galvanized coating prior to application of wet paint systems, together with life to first maintenance periods for duplex-coated articles in a variety of exposures (the predicted life to first maintenance relates only to the need for repair of the organic coating and so is likely to be much shorter than the life expected from use of the galvanized coating alone).<sup>44</sup> EN 13438 provides performance requirements for duplex systems involving powder organic coatings applied to galvanized articles.<sup>45</sup>

### 4.06.11 Applications for Hot Dip Coated Products

All industrial sectors use hot dip coated products of one form or another. [Table 5](#) illustrates a range of application sectors for hot dip coated products. The growing need for cost-effective, long-life, sustainable corrosion protection systems has led to increasing usage of hot dip coated products worldwide. The construction industry and street and outdoor furniture sectors

dominate the take up of hot dip galvanized products, followed by agricultural sector and many other, smaller, market segments. Development of coatings with greater formability for application to higher strength steel has increased the usage of these types of coatings in the vehicle manufacturing sector.

#### 4.06.12 Standards

The development of standards for hot dip coatings within the European region, through Comité

**Table 5** Applications for use of hot dip coated products

<i>Application</i>	<i>Examples</i>
Agricultural	Animal pens, buildings, cattle grids, farm machinery, gates, grain hoppers, glass houses, livestock trucks, and sprinklers
Building components	Balconies, downpipes, fire escapes, gutters, lintels, louvres, reinforcing bar, and window frames
Construction	Bridges, building frames, car parks, telecom masts, ski lifts, tunnels, siding/cladding, corrugated roofing
Industrial	Access bridges, cat ladders, checker plate, conduit, handrail, pipe bridges, stairways and walkways, and platforms
Marine	Boat hulls, buoys, chains, docking pontoons, fish farm equipment, handrailing, offshore platforms
Miscellaneous	Brackets, castings, fasteners, nails
Power generation/distribution	Cable tray, cooling towers, flues, power station equipment, pylons, transformer boxes, wind turbines
Storage and handling	Conveyor systems, cranes, drums, pallets, racking, and stillages
Street furniture	Benches, bollards, bus stops, crash barrier, lighting columns, manhole covers, palisade fencing, playground equipment, and safety barriers
Transport	Fencing, footbridges, rail gantries, motorway signal gantries, railway station platforms, trailers, and vehicle chassis
Automotive	Components, subframe, body-panels, fuel tanks, baffles, brackets, filler caps
Food	Packaging (cans)
Domestic	Mufflers, furnaces, ovens, ranges, heaters, water heaters, fireplaces, baking pans, air conditioner housings and drying ovens, lighting fixtures

Source: UK Galvanizers Association, 2007.

Européen de Normalisation (CEN), and on a global scale, through the International Standards Organisation (ISO), has burgeoned over the last decade. **Table 6** shows a selection of relevant international and European standards for hot dip coatings on articles. **Table 7** shows a selection of relevant American standards (developed by the American Society for Testing and Materials (ASTM) International). Where standards are specified, the latest dated document should be used.

#### 4.06.13 Recent and Future Developments

Since the previous edition was written, several new directions for development have emerged, and are likely to continue into the future:

**Table 6** Selected international and European reference standards relevant for specification and use of hot dip coated sheet/articles

<i>EN/ISO</i>	<i>Title</i>
ISO 752	Zinc ingots
ISO 9223	Corrosion of metals and alloys – Corrosivity of atmospheres – Classification
EN 1179	Zinc and zinc alloys – Primary zinc

**Table 7** Selected ASTM standards relevant to hot dip coating of steel sheet/articles

ASTM	Title
A90/A90M	Standard Test Method for Weight (Mass) of Coating on Iron and Steel Articles with Zinc or Zinc-Alloy Coatings
A123/A123M	Standard Specification for Zinc (Hot-Dip Galvanized) Coatings on Iron and Steel Products
A143/A143M	Standard Practice for Safeguarding Against Embrittlement of Hot-Dip Galvanized Structural Steel Products and Procedure for Detecting Embrittlement
A153/A153M	Standard Specification for Zinc Coating (Hot-Dip) on Iron and Steel Hardware
A308/A308M	Standard Specification for Steel Sheet, Terne (Lead-Tin Alloy) Coated by the Hot-Dip Process
A384/A384M	Standard Practice for Safeguarding Against Warpage and Distortion During Hot-Dip Galvanizing of Steel Assemblies
A463/A463M	Standard Specification for Steel Sheet, Aluminum-Coated, by the Hot-Dip Process
A653/A653M	Standard Specification for Steel Sheet, Zinc-Coated (Galvanized) or Zinc-Iron Alloy-Coated (Galvannealed) by the Hot-Dip Process
A792/A792M	Standard Specification for Steel Sheet, 55% Aluminum-Zinc Alloy-Coated by the Hot-Dip Process
A875/A875M	Standard Specification for Steel Sheet, Zinc-5% Aluminum Alloy-Coated by the Hot-Dip Process
A924/A924 M	Standard Specification for General Requirements for Steel Sheet, Metallic-Coated by the Hot-Dip Process
A1046/A1046M	Standard Specification for Steel Sheet, Zinc-Aluminum-Magnesium Alloy-Coated by the Hot-Dip Process

- Zinc alloy coatings to control reactivity in galvanizing and fabricated articles.<sup>46</sup>
- Development of zinc–aluminum–magnesium and composite coatings for continuous sheet galvanizing.<sup>47</sup>
- Development of lead-free coatings<sup>46</sup> and duplex coatings.<sup>48</sup>

Very recently, an explanation of the beneficial effects of magnesium alloying in zinc hot dip coatings has

emerged. As magnesium is added to zinc coatings, up to around 8 wt% magnesium, a magnesium-based oxide layer gradually replaces the zinc-based oxide layer. It is known that magnesium oxide has a higher band gap than do zinc oxide (5.2 eV compared with 3.5 eV, respectively), and therefore a lower ability to transfer electrons. This results in a reduced efficiency of oxygen reduction. As magnesium in the coating is further increased, the corrosion resistance does not improve and indeed decreases as hydrogen depolarization becomes easier in the higher magnesium content phases that then exist in the coating, for example, ZnMg. At this point, the optimal composition appears to be one that allows for bulk zinc metal to be present in the coating giving an anode, together with magnesium oxide in the surface layer, with its low ability to reduce oxygen.<sup>49</sup> Further improvements are being seen with zinc–aluminum–magnesium hot dip coatings whose mechanisms for improvement appear to be similar to that of zinc–magnesium coatings, but are not yet fully understood.<sup>50</sup>

**Abbreviations****ABS** Acrylonitrile–butadiene–styrene**AC** Alternating current**DC** Direct current**IMF** Institute of Metal Finishing (Birmingham, UK)**PNS** Post-nickel strike**TFS** Tin-free steel**4.07.1 Approach**

There are books and reviews dealing with electroplating which approach it as a commercial technology, a useful art, or an interesting process for scientific enquiry. In this case, the emphasis is on the production of coatings for the control of corrosion and the consequences of action taken at various stages of electroplating for the control of corrosion events. Corrosion control is not the sole function of electroplated coatings; indeed most authors play down corrosion control in favor of ‘more positive’ virtues such as decoration (sales appeal), reflectivity, wear resistance, solderability, or low contact resistance. However, to preserve these properties, it is essential to prevent corrosion; in essence, electroplated metal coatings are required to confer corrosion resistance together with one or more of the other properties, the nature of which provides the criteria on which selection of a coating is made. Corrosion protection is a common factor.<sup>1–7</sup>

**4.07.2 Origin**

The production of electricity by metallic corrosion in Volta’s pile (1786) was followed by the reduction of metal ions to metal by electrons at a metal–solution interface.<sup>8</sup> Electroplating is an application of electrodeposition to produce thin, coherent, adherent coatings of solid metal, and is one of the important methods for producing coatings. Brugnattelli,<sup>9</sup> a Professor of Chemistry at the University of Pavia, published an account of silver plating in 1800, and is said to have gold plated silver coins using Volta’s pile as early as 1805. Wollaston deposited copper (presumably a very small quantity) on silver wire using current from an electrostatic generator. Electrodeposition was developed energetically in the succeeding three decades, and by 1840, commercial electroplating had advanced to the stage where patent protection was being sought for various processes. The breakthrough was made in

1839–1840 through the discovery of cyanide as a versatile complexant for first silver and gold and later other metals. The main source of electricity for the first six or seven decades was the primary galvanic cell, and progress was aided by the invention of cells such as those of Daniell, Meidinger, Grove, and Bunsen, which were capable of delivering large currents for long periods without polarisation. Faraday discovered electromagnetic induction in 1831, and Pixii used the commutator in 1832 to produce a direct current generator, but it was not until about 1870 that several independent inventors used electromagnetic field coils to generate the heavy currents needed for electrolysis. Large scale electroplating enterprises were established by the latter part of the nineteenth century. In 1883, the Postal Telegraph Company of New York used 200 copper plating cells to deposit 250 kg day<sup>−1</sup> onto steel wire. Aqueous solutions have always been by far the most important electrolytes. There have been many investigations of nonaqueous solutions or ionic melts, and Davy deposited the alkali metals from the latter in 1807. Aqueous solutions and their associated pre- and postplating treatments are so well established that they are likely to remain preeminent for the immediate future.<sup>8–16</sup>

**4.07.3 Substrates**

Metallic substrates which are good electron conductors and nonmetallic ones which are not can both be electroplated with adherent coatings, but the preliminary procedures or ‘pretreatment’ differ markedly. The commonly plated metal substrates are mild and low-alloy steels, zinc alloys for diecasting, and copper or high-copper alloys like brasses, bronzes, and beryllium coppers. A large number of other alloys can be electroplated, but their use is restricted to particular industries, and they often require special pretreatments. Aluminum alloys, stainless steels, titanium alloys, and refractory metals are examples. The three major substrates are plated with corrosion control as one of the important objectives, but with less common substrates this may not be the case. There has been a rapid growth in electroplated parts made from plastic material. The main objective is to make the part look metallic for reasons of appearance rather than function. A complicated acrylonitrile–butadiene–styrene copolymer dispersion (ABS) was the first plastic material to be plated on a large scale. It was followed by polypropylene, and the development of plating grades of other plastics (e.g., polysulphone, polycarbonate, epoxide resins, glass-reinforced polyester) is

at hand. Metallic corrosion problems arise as soon as plastics have been plated, creating a new field for the corrosion enthusiast to investigate.

By exercising ingenuity, most nonconducting objects may be electroplated, and this is a long-established small-scale operation. The usual aim is artistic or a search for novelty, a good example being the preparation of a heavily gold-plated haggis for the 1973 conference of the Institute of Metal Finishing, which took place in Edinburgh.

## 4.07.4 Pretreatments

### 4.07.4.1 Metallic Substrates<sup>17-21</sup>

This is considered in detail in **Chapter 1.08, Stress Effects in High Temperature Oxidation**, but a brief review is relevant here in relation to electroplating.

Metallic articles arrive at the electroplating stage with a surface film of soil derived from earlier production processes. These are divided into three classes:

- Organic films, oils, greases, and perhaps polymeric films.
- Fine particles suspended in (a), often of siliceous material, that is, dirt.
- Films of the substrate oxide or other corrosion products.

With few exceptions, it is more efficient and economical to use at least two different pretreatments, that is, degreasing processes which deal with (a) and (b), and pickling processes which remove oxide and corrosion films. Degreasing comes first, as pickling processes fail on hydrophobic surfaces.<sup>17-21</sup>

#### 4.07.4.1.1 Degreasing

Hydrocarbon or mineral oils are removed by solvents; vapor degreasing with chlorinated solvents or emulsification, is a common alternative. Greases of animal or vegetable origin, which are fatty acids, alcohols, or esters, are removed with hot aqueous solutions of high-pH (alkaline degreasing). They react with alkali to form water-soluble soaps. Electrolytic alkaline degreasing is considerably faster than soak cleaning. The work, immersed in hot alkali, is usually the cathode. A mass of hydrogen bubbles formed at the solution-metal interface undermines and removes the grease very effectively; saponification takes place more slowly later. Ferrous metals may be degreased anodically, the metal surface becoming passive, but nonferrous metal anodes corrode in hot alkaline solutions. Anodic cleaning produces only half the volume of gas

(oxygen) and is less effective on that count. However, there is an advantage. During use, small amounts of metal enter the cleaning solution; other metals enter as impurities in the salts and make-up water. A thin metal film may be electrodeposited during cathodic cleaning, which if it remains can decrease the corrosion resistance of the main deposit. Anodic cleaning avoids this danger, even when the cleaning bath is contaminated. For steel and occasionally for copper alloys, a cleaning cycle is employed, with the work being cathodic for degreasing; but the current is reversed for the final few seconds, during which any thin film of metal impurity is removed by anodic dissolution.

Alkaline cleaning solutions are compounded from sodium hydroxide, trisodium phosphate (TSP), sodium silicate, sodium carbonate, soaps and detergents, and other materials. The higher the pH, the more effective is the saponification, but with nonferrous metals, the greater is the danger of corrosion. Zinc diecastings and aluminum need much less aggressive alkalis than those which are safe with steel. For aluminum and its alloys, a high concentration (10%) of sodium silicate acts as a corrosion inhibitor and as a cleaner.

To check the efficacy of grease removal, the alkali solution is rinsed away or neutralized by dipping in dilute acid. If, after removal from the acid, the draining metal surface remains wetted evenly all over for 30–60 s (or until it dries by evaporation), hydrophobic soils have been removed. Traces of grease cause the surface to dewet, and surface tension draws the water into separate droplets. This is the water-break test. Traces of grease which remain when the work is plated do not prevent electrodeposition, but are detrimental to adhesion and corrosion resistance by increasing the incidence of coating porosity.

Particulate dirt is usually removed together with the grease which binds it, although there are a few exceptions. Sheet steel may carry a 'smut' of finely divided carbon (or perhaps iron carbide) left from pickling processes in steelmaking. This is not removed with grease, and if evenly distributed, it is not apparent until the work is rubbed locally. Left in place, it leads to porous and poorly adherent coatings. While it can be removed by mechanical means, for example, vigorous brushing, this is impracticable when automatic plating machines are used. Steel which shows this defect may be unsuitable for plating.

#### 4.07.4.1.2 Removal of oxides and corrosion products

Oxide and corrosion-product films are removed by dissolution in aqueous solutions. Hydrochloric and

sulfuric acid are the most common. Concentrations and temperatures are varied according to the substrate. For mild steel, for example, cold 15 wt% HCl is suitable, but for zinc diecastings the concentration must be reduced to 0.25 wt%, and the pickling time must be kept very short to avoid excessive attack. Rust is more quickly removed by acid pickling when, in the prior degreasing stage, the work is made the cathode rather than the anode. Cathodic cleaning partially reduces rust to magnetite and iron, which undergo rapid reductive dissolution in the acid. Mixed acids containing wetting agents are supplied as proprietary mixtures; hydrochloric, sulfuric, and phosphoric acids are common. Inhibitors – generally amino compounds – may be added, but strongly adsorbed films of inhibitors or their breakdown products may cause trouble later. Electrolytic pickling is used for special purposes, but hydrochloric acid is unsuitable for this purpose because of its volatility and the possibility of chlorine evolution. Cathodic pickling of steel in 10–20 wt% sulfuric acid enables thick rust or scale to be dissolved without losing metal, which is cathodically protected. Anodic pickling in 42 vol.% (about 55 wt%) sulfuric acid is used to remove a thin surface layer from steel. A high current density is used and dissolution, which is under diffusion control, is uniform. After 10–20 s, the metal becomes passive and dissolution ceases. Disordered and fragmented metal produced by abrasion or machining is removed to leave a surface which favors good adhesion of an electrodeposit. Oxide and corrosion products on copper and its alloys may be removed in hydrochloric or sulfuric acids, less concentrated than that used for steel. Sulfuric acid allows the dissolved copper to be recovered and the acid to be regenerated by electrolysis. However, when copper alloys are cathodically degreased, cuprous oxide is reduced to loose copper particles which do not dissolve in acid. An electroplated coating over loose metal is likely to be defective. A much more aggressive mixture of sulfuric and nitric acids known as a bright dip or sometimes (wrongly) aqua fortis is used. This is a rudimentary chemical-polishing system and produces a bright surface from which the loose particles have been removed.

#### 4.07.5 Nonconductors

Plating plastic articles has become a widespread commercial process fairly recently. The main plastics in use at the time of writing are ABS and

polypropylene. Both replace diecast and pressed metal in various fields. Molded parts have smooth surfaces unsuited to producing adherent plate, and the first step is to ‘etch’ the plastic surface by using strongly oxidizing acids, usually chromic plus sulfuric acid mixtures. The plastic must have dispersed in its surface small areas more susceptible to oxidation than the surrounding matrix, and these are introduced in a variety of ways during manufacture. Etching produces a pattern of small pits. The second step is to produce within the pits and over the surface a fine metallic precipitate. One method is to dip in solutions of stannous and palladium salts in succession, which produces fine palladium particles, but there is a variety of proprietary processes available. The metal particles become nuclei for the deposition of a metal coating from an electroless plating bath. This is an aqueous solution of a metal salt containing a reducing agent that is able to reduce the metal ions to metal. The solution is unstable, but is compounded and used so that homogeneous electron transfer does not occur, and there is neither homogeneous precipitation of metal, nor heterogeneous precipitation on nonconducting surfaces, but only on the metallic nuclei on the plastic surface. Several electroless plating processes have been devised, but only those for copper or nickel are widely used for plastics. Once a continuous coating of metal has been produced, the substrate can be transferred to an electroplating bath for the application of any desired coating. Most plastic articles are finished with nickel and chromium.<sup>22–32</sup>

##### 4.07.5.1 Mechanical Pretreatments

Mechanical processes which cold-work a substrate have important effects on electrodeposits. Examples are grinding and abrasive polishing, grit and shot blasting, cold rolling, and severe cold deformation. They alter the metallurgical structure of the substrate, reducing the surface grain size and in some cases produce small crevices filled with nonmetallic debris. Abrasive processes which act parallel to the surface (e.g., grinding, polishing) may leave splinters and leaves of metal attached at one end but otherwise separated from the surface on which they lie. In addition, nonmetallic abrasive material is embedded in the surface. Surfaces which are neither annealed nor otherwise treated to remove mechanically disturbed surface layers, affect the structure and properties of metal electroplated over them, as mentioned below. In many cases, one result of the modification of the electrodeposit is to reduce the corrosion protection it affords. Where the same

topographical alteration of a substrate can be achieved by nonmechanical means, for example, electrochemical polishing, electrochemical machining, chemical milling, the surface left is not cold-worked and does not disturb an electrodeposit to the same extent.<sup>33–40</sup>

## 4.07.6 Plating Processes

### 4.07.6.1 Electroplating

The metallic substrate, clean and rinsed, is immersed wet in the plating cell. The base metals which are usually plated present an essentially metallic surface to the electrolyte, and the slight corrosive action of the rinse water in preventing the formation of any substantial oxide film is important. A critical balance of corrosion processes in the initial stages is vital for successful electroplating, and for this reason, there is a severe restriction on the composition of the electroplating bath which may be used for a particular substrate. This will be discussed later. The substrate is made of the cathode of the cell; it may be immersed without applied potential ('dead' entry) or may be already part of a circuit which is completed as soon as the substrate touches the electrolyte ('live' entry). Live entry reduces the tendency for the plating electrolyte to corrode the substrate in the period before the surface is covered by the coating. The main cathodic process is usually the reduction of dissolved ions to metal in the form of an adherent, coherent coating.

The ions reduced may be aquo cations, for example,

or oxyanions, for example,

or complex ions, usually cyanides, for example,

Cations are assisted by the electric field to migrate to the cathode. On the other hand, the field impedes the migration of anions, and diffusion has to overcome this. It is rare for metal reduction to be the sole cathode process, as water and other dissolved substances are reduced simultaneously. Many compounds are added intentionally to take part in the cathode process, with the object of modifying the nature of the coating. Such materials are called addition agents and are subdivided into classes on the basis of their

main effect (e.g., brighteners, levelers, grain refiners, stress reducing agents). In all aqueous solutions, water may be reduced: either

or

This reaction becomes thermodynamically possible whenever the cathode potential falls below

$$E = \frac{RT}{2F} \ln \frac{(a^2\text{H}^+)}{p\text{H}_2} \quad [1]$$

where  $R$  is the gas constant,  $T$  the temperature (K),  $F$  the Faraday constant, and  $p\text{H}_2$  is the relative partial pressure (strictly, the fugacity) of hydrogen in solution, which for continued evolution, becomes the total external pressure against which hydrogen bubbles must prevail to escape (usually 1 atm). The activity of water  $a\text{H}_2\text{O}$  is not usually taken into account in elementary treatments, as it is assumed that  $a\text{H}_2\text{O} = 1$ , and for dilute solutions this causes little error. Note that in some concentrated plating baths  $a\text{H}_2\text{O} \neq 1.0$  and neither is it in baths which use mixtures of water and miscible organic liquids (e.g., dimethyl formamide). However, by far the most important term is the hydrogen ion activity; this may be separated so that eqn [1] becomes

$$E = -\frac{RT}{2F} \ln p\text{H}_2 - \frac{2.303RT}{F} pH \quad [2]$$

As  $p\text{H}_2 \approx 1 (\approx a\text{H}_2\text{O})$

$$E \approx -0.059 pH \quad [3]$$

These considerations have been entirely on the basis of thermodynamics and take no account of the overpotential, which is dependent on the rate of the process and the nature of the surface at which the reaction occurs. For this reason, the rate of reduction of  $\text{H}^+$  or  $\text{H}_2\text{O}$  is usually low, and remains so to potentials from 0.5 to 1.0 V, below that given in eqn [1]. Even so, the instability of water is an insuperable obstacle to electrodepositing metals whose ions are so stable in aqueous solutions (e.g.,  $\text{Al}^{3+}$  aq.) that water reduction becomes the sole cathode process.

Much time has been devoted in recent years to study the mechanism of electrodeposition. Most investigators have assumed that electrodeposition should follow a mechanism akin to that for the deposition of a crystalline coating by condensation of a vapor. The

solvated metal ion approaches and adsorbs on the cathode, losing some of its solvation sheath as the cathode gains the requisite electrons. The adion, which is mobile, diffuses over the cathode surface until it reaches an atomic step. It adsorbs on the step, losing more water of solvation, and having its freedom reduced to diffusion along the step. Further desolvation and coordination follows when it reaches a kink in the step, at which stage it is immobilized. When other adions following this path eventually join and submerge the first, coordination with water in the electrolyte is exchanged fully for coordination with metal ions in the metallic lattice. This view of the mechanism of electrodeposition is plausible and compatible with both current views on metallic crystals and their defects, and certain properties of electrodeposits. It is, however, a preconceived notion, and considerable experimental difficulties in the way of producing evidence are responsible for both the numerous different investigations in the field, and the fact that the evidence produced is impressive more for its volume than its conclusive force.

Current enters through the metal–electrolyte interface of the anode, which is usually made from the same metal as is plated on the cathode. The anode dissolves replacing the metal lost at the cathode:

The overall process is metal transfer from anode to cathode via the solution. The form of anode corrosion is important, and materials may be added both to the anode metal and to the electrolyte, to influence it. There are important instances where an insoluble anode is used, and the anode reaction becomes the oxidation of water or hydroxyl ions: either

or

and also the oxidation of any other susceptible materials. Oxidation of water may occur at an anode, which was intended to be soluble, if the metal becomes passive. The minimum potential, above which the anode must rise before oxidation of water occurs, is:

$$E = E^0 + \frac{RT}{4F} \ln(pO_2 \times a_{H^{+}}^4) \quad [4]$$

In this equation,  $E^0$  is the standard electrode potential of the water/oxygen reaction, that is,  $-\Delta G_{H_2O}^0/nF$ . Simplifying, eqn [4] at 298 K becomes

$$E = 1.23 - 0.059 pH \quad [5]$$

There is often an overpotential of about 0.5 V before the rate of oxidation of water becomes rapid.<sup>41–43</sup>

#### 4.07.6.2 Aqueous Electrolytes

Aqueous solutions have a complex structure. Liquid water is anomalous; properties estimated by interpolation from those of neighboring hydrides in the periodic table fall wide of the observed properties. For example, estimated melting and boiling points are  $-43$  and  $-11$  °C, respectively. Molecular interaction (hydrogen bonding) imposes short range order in the liquid, which the anomalous properties reflect. Some of the crystal structure of ice is retained in the liquid, though the structure is less open, and water shares this peculiarity with diamond, silicon, and germanium, as in each case the liquid is denser than the solid at the melting point. A simple view of water is as a fluid with two species, small local regions with an ice structure and others with a strongly associated but irregular structure  $(H_2O)_n$ . The ‘icebergs’ and random groups are in dynamic equilibrium, exchanging individual molecules throughout the lifetime of the larger groups, which are not themselves permanent.

Water has a permanent dipole moment (strictly it is a quadrupole moment) caused by the asymmetry of the molecule and the greater electron affinity of oxygen. When soluble strong electrolytes, for example, nickel sulphate, dissolve, they dissociate completely, and the interactions between the charged ions and the dipole water molecules considerably modify the water structure. The small nickel ions with their high charge density will cause more disruption than the larger sulphate ion, but both become strongly associated with a sheath of water molecules (Figure 1). The bonding between the ion and solvation sheath confers a high degree of stability on the

**Figure 1** (a) Water molecule, dipole structure, (b) solvation of a small cation, for example,  $Ni^{2+}$  and (c) solvation of a larger anion, for example,  $SO_4^{2-}$ .

ions in aqueous solutions. The dipolar nature of the solvent, able to stabilize ions of either charge sign equally well, makes water an excellent ionic solvent. Ionic solvation destroys the ice-like component of the liquid with a result similar to that observed on melting, that is, a decrease in volume as the 'space-wasting' ice structure is removed, and many strong electrolytes have a negative volume of mixing.

Aqueous solutions of nonelectrolytes, especially of nonpolar solutes, may show the reverse effect and increase the proportions of ice-like components. The nonpolar part of organic electrolytes such as soaps and wetting agents may predominate in increasing the ice component. Thus solutes can be divided into two classes: structure making and structure breaking, and in some metal-finishing process solutions of both types of solute may be added. In certain cases, it is impossible to satisfy both, and there is a decrease in solubility of the least successful component. For example, a soap such as sodium palmitate, which in water is mainly

is very soluble, and the proportion of ice-like water increases to minimize interaction with the hydrophobic hydrocarbon chain. If sodium chloride is added to a concentrated soap solution, the ice-like structure is broken, and the increased concentration of 'free water' causes the palmitate to separate. Polar nonelectrolytes such as the lower alcohols have an even greater effect on the water structure than soaps. Being themselves capable of forming hydrogen bonds, they enter the 'iceberg' structure, increasing its stability. Methyl or ethyl alcohol added to solutions saturated with structure-breaking electrolytes, for example,  $\text{NiSO}_4$ , in a plating bath, can withdraw water from the ionic solvation sheaths to form ice-like water, and now it is the electrolyte whose solubility falls. Soap, on the other hand, is more soluble in alcohol-water mixtures.

The ability of water to be oxidized or reduced at the plating-bath electrodes is in practice an important advantage, though it has a few drawbacks. The drawbacks are overemphasized in textbooks and the advantages ignored. An ion which is much more stable towards reduction than water is unaffected in the region of the cathode during electrolysis. With the margin of polarization of 0.5–1.0 V, the manganous aquocation is the most stable that can be reduced in aqueous solutions, but because of the shortcomings of the metallic coating, manganese is not used, and the zinc aquocation is the most stable ion that can be

reduced in large scale electroplating. A drawback is that the aquocations of aluminum, titanium, zirconium, niobium, and tantalum are too stable. Their known corrosion resistance would make them important coatings, but they cannot be electrodeposited. On the other hand, there are numerous electrolytes whose presence is desirable in a plating bath but whose cations must not be reduced during electrolysis. The complete stability of cations like  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{NH}_4^+$ ,  $\text{Li}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Al}^{3+}$  is then an advantage. Should the cathode be depressed (accidentally) below the normal working value, they are safe from reduction as hydrogen evolution acts as a 'safety valve' for excessive currents. The products of water reduction, hydrogen gas and  $\text{OH}^-$  ions, are less likely to contaminate a large volume of valuable solution than are the reduction products of other materials.

Similar considerations apply to oxidation. An anion, which is considerably more stable than water, will be unaffected in the neighborhood of the anode. With a soluble anode, in principle, an anion only needs be more stable than the dissolution potential of the anode metal, but with an insoluble anode, it must be stable at the potential for water oxidation (eqn [4] or [5]), plus any margin for polarization. The metal salts, other than those of the metal being deposited, used for electroplating are chosen to combine solubility, cheapness, and stability to anode oxidation and cathode reduction. The anions most widely used are  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ,  $\text{F}^-$  and complex fluorides  $\text{BF}_4^-$ ,  $\text{SiF}_6^{2-}$ ,  $\text{Br}^-$ ,  $\text{CN}^-$  and complex cyanides. The nitrite ion is usually avoided because it is too easily reduced at the cathode. Sulfite, which is used for gold plating, is nevertheless too readily oxidized at the anode, and provides an example of an ion used in one instance despite its drawbacks. The oxidation of water at the anode is also a reaction which does not contaminate the solution.

Much laboratory work has been performed to develop nonaqueous plating baths, using either organic solvents or ionic melts. Insofar as the reduction of water is concerned, there are two rather different aims in view. Firstly, there is a search for solvents or melts sufficiently stable to allow electrodeposition of coatings of aluminum, titanium, etc., which is impossible with water as the solvent. Secondly, there is a need for a nonaqueous solvent for metals such as cadmium, whose electrodeposition from water, while practicable and satisfactory, is always accompanied by hydrogen which can embrittle cathodes of certain high strength steels and other alloys. Here, the aim is to avoid hydrogen discharge.

A practical drawback to the use of nonaqueous solvents is the accumulation of the by-products of solvent-electrode reactions leading eventually to the bath being poisoned.<sup>44</sup>

#### 4.07.6.3 Simple and Complex Ions

Amongst the common metals of the electroplating industry, only nickel is invariably reduced from its aquocation. Copper, silver, gold, cadmium, and zinc are normally deposited from solutions of complex cyanides; tin and chromium from oxyanions, and tin, in other cases, from a complex fluoride. Platinum-metal plating baths contain ions, all of which are complex; it is doubtful if any platinum-metal aquocation can exist in aqueous solution, as such is the high tendency of these metals to form complexes. If a ligand, such as cyanide, can displace water from an aquocation to form a complex ion, the complex must be more stable, and the deposition potential is always more negative for a complex ion than for the equivalent simple ion. Let the equilibrium between aquocation  $M^{n+}$ , ligand  $X^{x-}$  and complex ion  $\{M(X)_p\}^{(px-n)-}$  be:

and

$$K = \frac{aM^{n+} \times a^p X^{x-}}{aM(X)_p^{(px-n)-}}$$

where  $K$  is the instability constant for the complex ion,  $p$  is the coordination number. The potential below which deposition becomes possible is

$$E = E^0 + \frac{RT}{nF} \ln \frac{K \times aM(X)_p^{(px-n)-}}{a^p X^{x-}}$$

or

$$E = E^0 + \frac{RT}{nF} \ln K + \frac{RT}{nF} \ln \left( \frac{aM(X)_p^{(px-n)-}}{a^p X^{x-}} \right) \quad [6]$$

where  $E^0$  is the standard electrode potential for the simple ion-metal equilibrium. The two bracketed terms on the right of eqn [6] constitute a sort of ' $E^0$ ' for the complex ion, and as  $K$  is usually very small, the second term is negative.

Complex ions used for electroplating are anions. The cathode tends to repel them, and their transport is entirely by diffusion. Conversely, the field near the cathode assists cation transport. Complex cyanides deserve some elaboration in view of their commercial

importance. It is improbable that those used are covalent coordination compounds, and the covalent bond breaks too slowly to accommodate the speed of electrode reactions. The electronic structure of the cyanide ion is shown below.

Here, electrons are contributed by the carbon atom (x), the nitrogen atom (o), and the cation (•), for example,  $Na^+$  in the case of a sodium cyanide solution.

A soluble cyanide added to silver nitrate solution precipitates silver cyanide as an ionic compound:

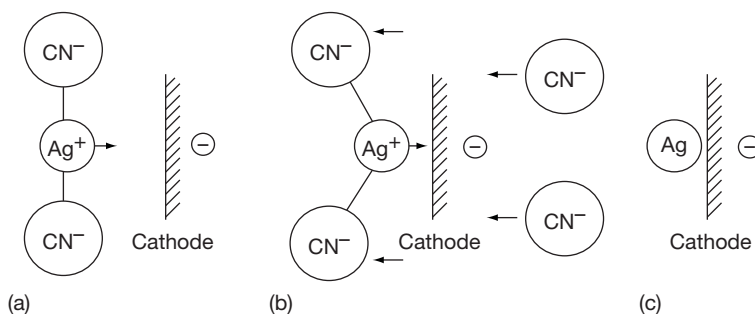

The precipitate redissolves in excess soluble cyanide, and the complex ion is probably an ion-dipole coordination compound, that is,

The solubility of  $Ag(CN)_2^-$  in water stems from the overall negative charge encouraging solvation with water dipoles, which uncharged  $AgCN$  does not. It is likely that the other cyanide complex ions of low coordination number have a similar structure.

When ions with this structure diffuse to the vicinity of a negative cathode, the ion is distorted by the field to become polarized, with the positive silver core nearest the cathode (see Figure 2). Once within a critical distance the field can assist transport of the distorted complex, discharge the silver core and eventually repel the released cyanide anions. There are several practical advantages in plating from complex cyanides. The reduction in deposition potential is most important in the application of relatively noble metals to base substrates, when avoiding severe cathode corrosion. The important case of the copper cyanide bath is discussed later. The impeded diffusion of the complex anion, the energy needed to polarize and reduce the anion, and the diffusion 'barrier' produced by the high concentration of cyanide near the cathode, all contribute to a high overpotential for electrodeposition, which aids the production of even coatings on cathodes of uneven shape. The cyanide ions released after discharge of the metal from the

**Figure 2** Ion distortion by the field in the vicinity of a negative cathode. (a) Diffusion of anion to cathode, (b) diffusion and migration of distorted complex and (c) release of  $\text{CN}^-$  ions and incorporation of  $\text{Ag}$  into the lattice.

complex modify the structure of the coating in a manner similar to that of addition agents, and it is probable that some cyanide is adsorbed. The result is that cyanide bath coatings are fine grained, hard, and may contain small amounts of carbon.

Some disadvantages stem from the same phenomena: impeded diffusion reduces the maximum practical rate of plating to well below that possible with aquocation baths. The cyanide ion is not entirely stable; both oxidation and reduction products accumulate, including carbonate. Carbonate is also formed in the alkaline cyanide baths (all cyanide baths are alkaline except some based on aurocyanides) by absorption of  $\text{CO}_2$  from the air, and it is necessary either to replace or purify baths periodically. Much has been made of the toxicity of cyanides, but the other process solutions used in plating are generally extremely toxic and corrosive or caustic, and it is necessary to treat them all with respect.

Oxyanions are important in chromium and tin plating. Although chromium plating baths have a simple formulation (chromium trioxide, sulfuric acid, and water), hydrolysis and side reactions form a variety of polychromate ions. The cathode reactions are numerous and imperfectly elucidated; only about 5% of the charge passed produces chromium. As in cyanide baths, the by-products behave as addition agents. The grain size of chromium electroplated under the normal conditions is the smallest encountered amongst metals. Tin coatings plated from stannate solutions are reduced from the  $\text{Sn}(\text{OH})_6^{2-}$  ions, and are fine-grained.

The platinum-group metals are necessarily plated from complex solutions, as all platinum-metal salts form complex ions in water. The development of aqueous baths has hinged upon finding complex ions sufficiently unstable to be reduced; all the platinum group cyanides are far too stable. Because all the platinum metals are good catalysts for hydrogen

evolution (high exchange current density) there is no useful margin of hydrogen overpotential over that predicted by eqn [2]. Nevertheless, aqueous plating baths have been devised for the entire platinum group, although only palladium, rhodium, and platinum find commercial use at present.

The complex cyanides of transition metals, especially the iron group, are very stable in aqueous solution. Their high coordination numbers mean the metal core of the complex is effectively shielded, and the metal–cyanide bonds, which share electrons with unfilled inner orbitals of the metal, may have a much more covalent character. Single electron transfer to the ferricyanide ion as a whole is easy (reducing it to ferrocyanide, with no alteration of coordination), but further reduction does not occur.<sup>45</sup>

#### 4.07.6.4 Conducting Salts, Addition Agents, and Other Ingredients of Plating Baths

Plating baths contain a number of salts and compounds in addition to those of the ion to be reduced to metal. Much commercial electroplating is from ‘proprietary’ solutions whose use is covered by patents, and which are supplied completely or partly compounded. The precise composition is generally a trade secret, and the patents may sometimes be very widely drawn to include a larger range of compositions and ingredients than is successful. A broad classification of additional ingredients includes the following:

- Those which maintain certain conditions but do not take part in electrode reactions; examples are electrolytes added to improve conductivity, pH buffer systems, and ions which maintain complex ion equilibria.
- Those which take part in the anode reaction, added to promote efficient dissolution of a soluble anode.

- (c) Those which take part in the cathode reaction by adsorption, codeposition, or both, or by modifying the reaction; these ingredients alter the structure and properties of the coating and have an important bearing on its corrosion properties. The term addition agents is generally used for this class.

A particular ingredient often acts in more than one category.

Conducting salts are usually sodium, potassium, or ammonium salts, or the acid of a stable ion already present from other ingredients. Apart from energy conservation, the higher the conductivity of a bath the better the distribution of thickness on complex shapes.

Addition agents are subdivided according to the main effect they have on the coating, that is, grain refiners, brighteners (primary), brighteners (secondary), levelers, stress reducers, and antipitting agents. Apart from the last, all these addition agents modify the growth process profoundly. They may be the ions of foreign metals which can codeposit, or polar or ionic organic materials. They introduce irregular atoms or molecular fragments into the metal lattice or grain structure of the main metal of the coating, and alter the crystal structure. The macroscopic results are suggested by the terms: smaller grain size, mirror-like surface, or a relatively smooth (level) surface on an initially rough substrate. These characteristics are not achieved without corresponding disadvantages. Foreign material from the addition agent is incorporated, up to 5% by weight for metallic codeposition, less for organic agents. First- and second-order tensile stresses usually increase, hardness rises, and ductility falls. First-order tensile stress can exceed the tensile strength of the coating, but for some metals, particularly nickel, addition agents (stress reducers) are known which decrease first-order stress, though second-order stress is not reduced. The mechanical results are detrimental to corrosion protection, but the topographical results, fine grain, and level and bright coatings, are favorable. The chemical results, on the evidence available, vary. The most extensively investigated case is nickel. Here, it is almost universal practice to employ several addition agents together in a bright plating bath, one of which causes the incorporation of a small amount (about 0.02%) of sulfur, and reduces the corrosion resistance of bright nickel. There are other systems (benzotriazole brighteners in copper, aldehyde-amine brighteners in tin) which enhance corrosion resistance.<sup>46-49</sup>

#### 4.07.6.5 Electroplating Anodes

The anode is usually soluble, and is made from a high purity form of the metal being deposited, or occasionally from an alloy. A soluble anode is often the cheapest and most convenient means of replacing the metal reduced at the cathode. Effective anode corrosion is important, and different examples present a variety of types of dissolution.

Copper anodes in the acid sulphate bath are an example of active anodic dissolution. They etch uniformly with low polarization at 100% efficiency, forming little anode debris or sludge. Idle anode corrosion is very slow with dissolved oxygen reduction as the cathodic reaction. Copper anodes in the cyanide bath corrode easily provided that there is sufficient excess or 'free' cyanide present. Polarization is higher than in the acid bath, with a much lower maximum current density. At high current densities, the rate of dissolution of copper exceeds the rate of supply of cyanide ions needed to form the cuprocyanide complex, and blue cupric aquocations form. Eventually, the anode becomes passive and evolves oxygen. For special purposes where anode area is limited (e.g., in a Hull cell), an insoluble mild-steel anode avoids these troubles. A proportion of insoluble anodes or alternate use of soluble and insoluble ones is necessary, because anode efficiency exceeds cathode efficiency, and the metal content of the solution would rise continually if soluble anodes alone were used.

Nickel is normally plated from mixed solutions of nickel sulphate and chloride using soluble anodes. The standing potential of pure nickel anodes indicates they are passive in the idle bath, while in operation dissolution is by pitting corrosion brought about by chloride (Figure 3). In all sulphate solutions, nickel anodes are passive and insoluble. Dissolution is aided by adding small amounts of sulfur or carbon to the nickel anode, which aid the breakdown of passivity ('depolarized anodes'). Nickel anodes produce a fine particulate 'anode sludge'; anode bags of finely woven cloth are used to retain much of this, and continuous filtration is needed to remove the rest, otherwise the corrosion resistance of the coating is severely degraded. Nickel can be used in the form of small 'chips' in baskets of titanium mesh. The titanium is passive and the surface is effectively insulated from electrolytic current exchange, but electrons released by the dissolving chips of nickel are able to pass via the metal-semiconductor contact with the basket to the outside circuit. Anode efficiency slightly exceeds cathode efficiency, but not sufficiently to increase the metal

**Figure 3** Part of an anode from a nickel plating bath, showing dissolution by pitting corrosion.

concentration, unless rigorous precautions are taken to return all the solution lost on surfaces removed from the bath.

Tin anodes dissolve by etching corrosion in acid baths based on stannous salts, but in the alkaline stannate bath, they undergo transpassive dissolution via an oxide film. In the latter, the  $\text{OH}^-$  ion is responsible for both film dissolution and for complexing the tin. Anodes must not be left idle because the film dissolves and thereafter corrosion produces the detrimental divalent stannite oxyanion. Anodes are introduced 'live' at the start of deposition, and transpassive corrosion is established by observing the color of the film (pale yellow for correct operation) and the anode polarization, and by adjusting the immersed area. The anodes retain a smooth, quasipolished surface, and no anode bags are needed. An alternative, where anode filming is inconvenient, is to use insoluble (passive) mild-steel anodes, and replaces tin by adding a colloidal dispersion of stannic oxide.

Chromium plating from hexavalent baths is carried out with insoluble lead-lead peroxide anodes, as chromium anodes would be insoluble (passive). There are three main anode reactions: oxidation of water, reoxidation of  $\text{Cr}^{3+}$  ions (or more probably complex polychromate compounds) produced at the cathode, and gradual thickening of the  $\text{PbO}_2$  film. The anode current density must balance the reduction and reoxidation of trivalent chromium so that the concentration reaches a steady state. From time to time, the  $\text{PbO}_2$  film is removed as it increases electrical resistance.

Gold plating is another process where insoluble anodes are the rule. Soluble gold anodes would be technically satisfactory in some baths, but too tempting to thieves. A factor in their decline is the disappearance of gold coins, whose temporary sojourn in the anode circuit is alleged to have provided a form of corrosion beneficial to gold platters of earlier times. Insoluble stainless-steel anodes are now widely used, with graphite, platinized titanium, and platinum mesh as alternatives. All suffer gradual deterioration. Stainless-steel anodes are pitted, especially in areas of high current density, and the corrosion products may eventually give trouble. Platinized titanium sheds its platinum coating, becoming steadily more polarized. Platinum anodes used with cyanide solutions slowly corrode.

The potentials and corrosion data for some anodes in typical plating baths are listed in [Table 1](#).<sup>50,51</sup>

With the exception of  $\text{Pb/PbO}_2$  for chromium plating, the main or even sole anode reaction is oxygen evolution from water. Selection of insoluble anode materials traditionally only took account of mechanical stability and corrosion resistance, and not of the evolution overvoltage which usually lies in the range 1–3 V. This represents a significant (and unproductive) proportion of the total cell or tank voltage drop of 5–9 V. Consequently, searches for anodes with lower overvoltages have led to adoption of the so-called catalytic anodes, which in the context of chlorine and seawater cathodic production technologies have been termed dimensionally stable anodes (DSAs). These were originally based on titanium substrates coated with platinum; product development has led to niobium or tantalum substrates with palladium, iridium, ruthenium, and mixed oxide coatings depending upon the application. In particular, the use of mixed oxides on titanium has established a reputation as the most catalytic anode available. Such anodes are specialist products and offer good service lives when carefully chosen.

However, the criteria for that reputation have been very misleading. They have been based on chlorine electrochemistry initially and later the oxygen reaction itself without regard to side reactions which might occur. One class of side reaction has proved to be problematical, that is, the possible oxidation of organic additives in solution for the purposes of brightening, leveling, wetting, etc. This has always been recognized as a loss, because of the slow oxidation by air used for agitation in industrial operations, but the loss has increased substantially and unacceptably since the introduction of catalytic anodes. The remedy may therefore be threefold:

**Table 1** Behavior of anodes in plating baths

Plating bath	Anodes	Corrosion process		Current density ( $\text{Am}^{-2}$ )	Potential (V) (vs.SHE)
		Idle	Working		
1. Watts' nickel $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ , 330 $\text{gl}^{-1}$ $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ , 45 $\text{gl}^{-1}$ $\text{H}_3\text{BO}_3$ , 30 $\text{gl}^{-1}$ pH 2.5 55 °C	Nickel slab	Passive	Pitting	0 65 130 195	+0.08 +0.23 +0.27 +0.30

- be more careful in the selection of anode by distinguishing between reductions of the oxygen overvoltage;
- introduce an organic reductant to be 'sacrificially' oxidised by the anode, for example, ascorbic acid;
- introduce an inorganic redox metal ion, for example, iron, to divert the oxidizing tendency.

The first choice is clearly the best, because it avoids further additions, which may cause build-up of products and be more expensive. Furthermore, the other choices are patented. The incentive is obvious – the

saving of 1–2 V or 10–15% of power supplied to the process. Other uses can also be identified; for example, the oxidation of  $\text{Cr}^{3+}$  to  $\text{CrO}_4^{2-}$  in a solution drag-out recovery operation for which diamond-like coatings may be the best. Similarly, the use of a selected anode can achieve oxidation of  $\text{CN}^-$  in a cyanide destruction stage of effluent treatment.<sup>52–55</sup>

#### 4.07.6.6 Corrosion of the Cathode

At the start, the cathode is invariably a metal different from that to be deposited. Frequently, the aim is to

coat a base metal with a more noble one, but it may not be possible to do this in one step. When a metal is immersed in a plating bath, it will corrode unless its potential is sufficiently low to suppress its ionization. Fortunately, a low rate of corrosion is tolerable for a brief initial period. There are cases, where even when a cathode is being plated at a high cathodic (net) current density, the substrate continues to corrode rapidly, because the potential (determined by the metal deposited) is too high. No satisfactory coating forms, if the substrate dissolves at a high rate concurrently with electrodeposition. This problem can be overcome by one or more of the following procedures:

- The use of a complex anion bath.
- The use of a 'strike' bath.
- The use of intermediate electrodeposits (undercoats or underplates).

The principles are illustrated by the following important commercial examples.<sup>52–57</sup>

#### 4.07.6.6.1 Zinc diecastings: complex baths and undercoats

Diecastings are made from zinc with up to 8% aluminum, but from the viewpoint of corrosion they behave like zinc. Diecast parts are often plated with nickel and chromium for protection and decoration, but when zinc is immersed in a typical nickel plating solution, it corrodes rapidly. There are two cathodic reactions: hydrogen is evolved and spongy nickel precipitates. If a diecasting is immersed 'live,' corrosion and electrodeposition occur together as the potential for nickel deposition still leaves the cathode too positive to suppress zinc corrosion (Figure 4). Standard practice is first to plate the zinc with an undercoat of copper, which is too noble to evolve hydrogen or reduce nickel ions. In the bath to which the data of Figure 4 are applied, the potential of copper was +0.042 V. Prolonged immersion led only to slow copper corrosion, with the reduction of dissolved oxygen as the cathodic reaction. This does not interfere with satisfactory nickel plating, and is entirely suppressed by live entry. The problem of applying a copper undercoat is solved by using the cuprocyanide complex bath. The acid cupric bath would present a worse problem than the nickel bath, with its lower pH and the greater oxidizing power of the cupric ion. The stabilities of zinc and copper are reversed in alkaline cyanide, and zinc will not displace copper from cuprocyanide. Zinc immersed in the cuprocyanide bath can corrode to form either zincate

**Figure 4** Corrosion diagram for a zinc diecasting in a nickel plating bath, pH 2.2. There are two possible cathodic reactions, hydrogen evolution (H) and nickel ion reduction (N). The corrosion current  $i_{\text{corr}}$  is the sum of the partial cathode currents. Even with 'live entry' the potential ELE is still too high to suppress corrosion, though the rate is reduced to  $i_{\text{corr}}$ .

or a complex zinc cyanide ion  $\text{Zn}(\text{CN})_4^{2-}$ , with two possible cathodic corrosion reactions, that is, dissolved oxygen reduction or hydrogen evolution. However, high polarization prevents either supporting rapid corrosion, and the situation is like that for copper in the nickel bath; a sound coating is possible and live entry suppresses corrosion. Once a coherent copper coating envelopes the zinc, the part is rinsed and transferred to the nickel bath.

The cuprocyanide plating bath is invaluable in numerous similar cases, where a base substrate cannot be plated directly with the chosen coating. Steels, brass, bronze, beryllium copper, and other substrates are copper underplated. Aluminum articles are ennobled, usually in two stages, that is, first coated with zinc, which is in turn copper plated as described. Such is the utility of the cuprocyanide bath in circumventing cathode corrosion that although copper finds no significant use as a coating in its own right, cuprocyanide baths are found in almost every electroplating establishment.

#### 4.07.6.6.2 Silver plating: 'strike' baths

A 'strike' is usually a solution of special composition in which electroplating is initiated. After a short period of 10–150 s, the cathode is transferred to a

normal bath. The term strike is also used when plating is initiated in the normal bath, but for 10–150 s under very different conditions (often much higher current density), continuing normally afterwards. Silver is electroplated from argentocyanide anions, that is,  $\text{Ag}(\text{CN})_2^-$ . The bath is alkaline and contains ‘free’  $\text{CN}^-$ . The argentocyanide ion is the least stable of the soluble complex cyanides, and therefore,  $\text{Ag}(\text{CN})_2^-$  is a strong oxidizing agent towards other metals which form soluble cyanide complexes. Generally, the reaction

proceeds as written where M is a more base metal of valency  $n$ . Copper, gold, zinc, iron, etc. are all base metals by comparison, so a copper undercoat does not solve the problem. An immersion deposit of silver leads to blistering and loss of adhesion, if electrodeposition is continued over it. The ‘nobility gap’ between copper and silver can be bridged by combining a shift in the equilibrium of eqn [7] with live entry. As a first step, the cathode may be given a copper undercoat. The deposition potential for silver (special case of eqn [7]) is

$$E = E^0 + \frac{RT}{F} \ln K_{\text{instab.}} + \frac{RT}{F} \ln \frac{a\text{Ag}(\text{CN})_2^-}{a^2\text{CN}^-} \quad [8]$$

where

$$K_{\text{instab.}} = \frac{a\text{Ag} + a^2\text{CN}^-}{a\text{Ag}(\text{CN})_2^-} = 1.8 \times 10^{-19}$$

At 298 K, eqn [8] is

$$E = -0.310 + 0.059 \log \frac{a\text{Ag}(\text{CN})_2^-}{a^2\text{CN}^-} \quad [9]$$

and may be depressed by reducing the ratio in the last term. Therefore, a silver strike bath has a small concentration of metal and a large concentration of free cyanide. Equation [7] shows that a high concentration of free cyanide further decreases the nobility of the substrate, so some of the advantage is lost. One way of redressing the balance would be to have the substrate complex  $\text{M}(\text{CN})_p^{(p-n)-}$  present in solution. Silver strike baths are formulated with cuprocyanide in solution, but curiously these are usually recommended for striking steel, while those recommended for copper alloys omit the cuprocyanide. The author uses the cuprocyanide silver strike for ferrous and copper alloys alike. The combination of low silver and high cyanide concentrations means the cathode

potential at a relatively high current density is very low, and both charge transfer and diffusion polarization are high. With live entry, the low potential suppresses substrate ionization, and a detrimental immersion deposit of silver is avoided. A thin underplate – called a flash – is deposited from the strike, after which the normal bath is used. Dilute strike baths working at high current density cannot deposit thick coatings; continued electrolysis produces incoherent, powdery material. They have a low cathode efficiency and evolve considerable hydrogen.

#### 4.07.6.6.3 Electroplating passive alloys

Another application of strike baths reverses the case illustrated in the previous example. The strike is used to promote a small amount of cathode corrosion. When the passivation potential of a substrate lies below the cathode potential of a plating bath, deposition occurs onto the passive oxide film and the coating is nonadherent. Stainless steel plated with nickel in normal baths retains its passive film and the coating is easily peeled off. A special strike bath is used with a low concentration of nickel and a high current density, so that diffusion polarization (transport overpotential) depresses the potential in the active region. The bath has a much lower pH than normal. The low pH raises the substrate passivation potential  $E_{\text{pass}}$ , which theoretically follows a relation

$$E_{\text{pass.}} = E_{\text{pass.}}^0 - 2.303 \frac{RT}{F} \text{pH} \quad [10]$$

When stainless steel is ‘struck,’ the passive film is reduced and an adherent flash of nickel forms on the active metal surface. Deposition is continued in a normal bath.

Electroplating aluminum and its alloys require a similar technique. In aqueous solutions, it is impossible to lower the potential sufficiently to reduce an alumina film, so the substrate is immersed in a strongly alkaline solution capable of dissolving it:

The solution also contains a high concentration of zinc (as zincate), which is noble relative to aluminum. As metallic aluminum is exposed, it corrodes, reducing zincate ions and forming a coating of zinc:

The immersion deposit is necessarily somewhat defective, for the reasons already mentioned, though immersion deposits from complex ions are finer grained and more satisfactory than those reduced from aquocations. The zinc coating is, under the best conditions, an acceptable basis for a copper undercoat from the cuprocyanide bath, on which other coatings can be plated, but there is usually a fair proportion of rejects in commercial operation. Other processes similar in principle use tin or bronze immersion coatings.<sup>56–61</sup>

#### 4.07.6.6.4 Service corrosion effects

Undercoats, 'flash' deposits produced by strike baths, and immersion deposits are potential sources of weakness. If their structure is faulty, it affects the subsequent layers built on the faulty foundation. The greater the number of stages, the higher is the probability of faults. Additional metal layers can create bimetallic corrosion cells, if discontinuities appear in service. The layer of copper beneath cadmium plate on aluminum (using a zincate plus cuprocyanide deposition technique) can cause corrosion problems. When aluminum is plated with nickel and chromium, rapid service corrosion in the zinc layer causes exfoliation.

#### 4.07.6.6.5 Corrosion potentials in plating baths

The standing potentials of steel and copper (before application of current) are shown in Table 2,

together with the standing potential of the plated metal and the potential below which hydrogen should, in theory, be evolved. The potential of the cathode during deposition at a typical current density is also given.

#### 4.07.6.6.6 Agitation and high-speed electrodeposition

There are a number of applications for electrodeposition where high speed is the essence. These include coated strip (e.g., tinplate and galvanized steel), electroforming, and jet plated connectors/contacts. Such high speeds can be achieved either by exploiting solution characteristics or by applying agitation techniques. In simple terms, this can be understood by consideration of the Nernst diffusion equation, where the limiting current density is defined as,

$$i_L = nFCD/\delta(1 - t)$$

Thus  $i_L$  is maximized by increasing  $C$ , the metal concentration in solution, through using near-saturated solutions, selection of highly soluble salts or complexes, or increasing  $D$ , the diffusion coefficient, by using high temperatures. Alternatively it can be maximized by minimizing  $\delta$ , the cathode diffusion layer thickness, by agitation or reducing  $t$ , the transport number, or by using highly conducting solutions through use of support salts (e.g., acids) in solution. In practice, all these can be exploited within the

**Table 2** Corrosion potentials of substrates of copper and steel, plated and unplated in same plating solutions

Plating bath	Copper	Steel	During plating	Plated copper	Plated steel	Hydrogen evolved below

Deposition potential is accompanied by current density ( $A\ m^{-2}$ ) in parentheses; the plated substrate's coating thickness was 2.5 mm. The final column gives the potential below which hydrogen evolution is possible; only in the cuprocyanide is it observed.

constraints of practicality, such as solution boiling and evaporation, heat loss costs, effluent treatment, etc. Thus, high speed solutions have been formulated for tin, zinc, nickel, gold, and silver using these principles.

Agitation has been more problematical. In the past, poor distinction has been made between solution mixing and diffusion layer thickness reduction. Traditional methods of cathode reciprocating movement and air bubbling or sparging are simple and cheap, but not very effective in the context of high-speed electrodeposition. Consequently, other techniques have been developed. Moving the cathode at high velocity is very effective provided it has symmetry of shape and can be done equally for all points on the deposition surface, for example, coating of continuous strip or wire substrates, or rotation of the cathode is possible as for cylinders, flywheels, tubes, bearings, etc. Alternatively, pumping the solution along or at the electrode interface is feasible by using focused jets or capillary-type gaps at the interface. The use of submerged eductor jets has become ecologically important, because there is little or no atmospheric spray produced and the venturi-induced flow can be substantially greater than the direct pumped flow.

Specialist forms of agitation have been developed for certain types of process. For example, deposition of composite coatings requires the particles to be suspended in solution and captured by the growing deposit. This is difficult with pumped flow agitation, where the particles are in fast continuous movement. In these situations vibratory agitation may be best or the solution could be made more viscous and agitation disregarded.

Comparison of the efficacy of agitation techniques has always been problematical because speed *per se* is inadequate – deposit quality must be assured. Theoreticians may prefer to define diffusion layer thicknesses or mass-transport numbers, but in practical terms the current density to attain a given deposit quality is easier to measure. From this, an agitation enhancement factor (EF) can be used for comparison, the EF value for a static solution being taken to be unity. Typical values are then as follows:

Cathode reciprocation	EF = 2
Air bubbling	2–5
Cathode movement	5–20
Cathode rotation	5–50
Jetting/eductor flow	10–25

Distinction should be made between agitative fluid flow and ultrasonic agitation. Ultrasonics are effective at displacing solids from interfaces in a cleaning mode and for modifying physical properties of the growing deposit but are not specifically effective at moving or thinning the liquid-phase diffusion layers.<sup>62–64</sup>

#### 4.07.6.6.7 Pulse plating

The use of pulsed current as a means of improving deposition rates and yielding improved deposits is a development of periodic reverse techniques, long used in the metal extraction and refining industries to produce smoother/leveled deposits. The reasoning was that high currents may give high deposition rates but generally yield rougher surfaces. However, reversing the current for a short time can ideally cause preferential anodic dissolution of the protruberances, thereby, leading to smoother surfaces. Thus a degree of inefficiency of overall production can be withstood in the attainment of better deposit surfaces. The times for forward and reverse currents are usually of the order of minutes.

While it may be easy to use sine wave alternating current waveforms, this is limited to 50 or 60 Hz and square waves are usually generated by an electronic waveform generator. The waves themselves may be on/off, but more usually, pulse/reverse, superimposed pulses, duplex pulse, etc. The choice depends upon intention with regard to electrode kinetics or mass transfer, electrocrystallization modification, deposit properties, etc. Furthermore, the technique has been explored for virtually every metal and alloy, which can or has been researched. Some metals, alloys, and solutions are more susceptible than others although in some cases the systematic research may not have been adequate. Successes have commonly been to modify deposit grain size and stress, to improve surface smoothness, distribution and brightness, to increase net deposit rates, and to enable layered deposits to be produced. The literature is now so large that it must be referred to by search engines and not general reviews.

When the time intervals are of seconds or less, the term pulse plating has become usual, for which a number of terms must be defined:

- The waveform is the shape of the current/time graph; it is usually square but could be sine wave. The pulses may be forward only or pulse/reverse (forward and negative). Other patterns are possible.

- The pulse frequency is the number of pulse cycles per second.
- The duty cycle (%) is the on time related to the total time.
- The mean current is the duty cycle  $\times$  the peak current

Many plating processes have been studied but relatively few have been used industrially or commercially. A number of reasons can be noted, especially the cost of pulsing large currents because of the dissipation of energy; but a particular reason is that each metal and solution has its own characteristics, which normally have to be individually studied or optimized, with transposition from another system only rarely successful. Consequently, apparent failure is often because of lack of perseverance! Puipe and Leaman in 1986<sup>65</sup> have demonstrated the huge stock of research data; what is lacking is this perseverance.

#### 4.07.6.7 Factors Influencing Structure

##### 4.07.6.7.1 Substrate effects: epitaxy and pseudomorphism

Both the words epitaxy and pseudomorphism are derived from classical Greek, the former meaning literally, close to or close upon an arrangement, row or series (technically an arrangement imposed upon a skin or layer, for example, an electrodeposit, which is close upon a substrate) and the latter, false form (technically a mineral or crystal displaying a form more characteristic of another material than its usual one). For many years, the two terms were held to be synonyms for one phenomenon in electrodeposits. Since 1936, it has become clear that there are two related phenomena, on each of which one of the names is bestowed. Not all authors recognize this, nor is the usage employed here adopted uniformly. Both phenomena are of great practical importance.

Pseudomorphism received methodical study from about 1905. A microsection taken across the interface between a substrate and an electrodeposit shows the grain boundaries of the former continue across the interface into the deposit (Figure 5). As grain boundaries are internal faces of metal crystals, when they continue into the deposit, the latter displays in the form of the substrate. Hotherhall's 1935 paper contains numerous excellent illustrations with substrates and deposits chosen from six different metals, crystallizing in different lattice systems and with different equilibrium spacing. Grain boundary continuation

**Figure 5** Pseudomorphism; grain boundaries in the substrate (S) are continued in the electrodeposit (D).

and hence pseudomorphism is evident despite the differences.

Epitaxy is a relation on the atomic scale between substrate and electrodeposit. Imagine that the interface of the microsection is magnified about 107 times so that the rows of atoms in the metal lattice become visible. If the deposit shows epitaxy, there will be an ordered and regular relation between substrate and deposit atom positions (Figure 6(a)). A nonepitaxial deposit shows no such relation (Figure 6(b)). Direct experimental demonstration of epitaxy was first made in 1936 by Finch and Sun. Earlier, metallographers argued that pseudomorphism (which they could see) meant there must be epitaxy (which they could not), as grain boundaries are surfaces where the direction of lattice rows of atoms changes; if epitaxy were assumed to exist, pseudomorphism should result. Reversing the argument, pseudomorphism was taken as evidence for epitaxy (Figure 6(c)).

Electron diffraction investigations showed that epitaxy did indeed exist when one metal was electrodeposited on another, but that it persisted for only tens or hundreds of atomic layers beyond the interface. Thereafter, the atomic structure (or lattice) of the deposit gets altered to one characteristic of the plating conditions. Epitaxy ceases before an electrodeposit is thick enough to be seen with an optical microscope, and at thicknesses well below those at which pseudomorphism is observed.

Epitaxy reflects the formation of metallic bonds between the dissimilar atoms at the interface. When the two metals crystallize in different systems, their relative orientation is that which promotes the maximum coordination and the maximum metallic bonding. The stability achieved by epitaxy overrides any lost because of the lattice strains imposed. These strains may be considerable; 'stresses' calculated from the bulk elastic moduli are correspondingly high, and sometimes puzzle the uninitiated if they

**Figure 6** (a) Coordination across a substrate S-electrodeposit D interface on the atomic scale produces epitaxy, (b) a nonepitaxial deposit has no coordination and (c) epitaxy would be expected to produce grain boundary continuation at the interface, though in fact grain boundaries often continue to thicknesses far greater than those at which epitaxy disappears.

exceed the bulk tensile strength. It is an oversimplification to regard the interface as being highly stressed; were the 'stress' which seems to be parallel to the interface reduced by some means to zero, the energy that would have to be put into the bonds normal to the interface would be much greater than that released. The simple concept of stress in a homogeneous alloy is not applicable to the peculiar case of a substrate-electrodeposit interface. The latter is unique in having metallic bonds carried across a very sharp boundary.

The practical result of epitaxy is a very high degree of adhesion between coating and substrate. The force needed to separate the interface is similar to that needed to break the metals on either side. Where a true metallic bond forms at an epitaxial interface, it is only possible to measure adhesion if the bond is the weakest of the three near the interface. An adhesion test based on breaking the joint indicates only which of the three is weakest. For practical purposes, any epitaxial joint will have strength more than adequate for service conditions.

Nonepitaxial electrodeposition occurs when the substrate is a semiconductor. The metallic deposit cannot form strong bonds with the substrate lattice, and the stability conferred by coordination across the interface would be much less than that lost by straining the lattices. The case is the converse of the metal-metal interface; the stable arrangement is that in which each lattice maintains its equilibrium spacing, and there is consequently no epitaxy. The bonding between the metallic lattice of the electrodeposit and the ionic or covalent lattice of the substrate arises only from secondary or van der Waals' forces. The force of adhesion is not more than a tenth of that to a metal substrate, and may be much less.

Epitaxial growth is prevented if semiconducting films of grease, oxide, sulfide, etc. cover the cathode surface. These occur when pretreatment is inadequate, when plating baths are contaminated, or when, as with stainless steel, aluminum, titanium, etc. an oxide film reforms immediately after rinsing. Low adhesion resulting from nonepitaxial electrodeposition is used in electroforming to promote easy separation of deposit and substrate. When semiconductors or nonconductors are to be electroplated, a form of dovetail mechanical joint (achieved as outlined above) is essential. Means similar to those for stainless steel and aluminum have been devised to deal with other alloys, which are passivated readily. Sometimes, even with special methods, some oxide remains so that the electroplated coating is anchored only by small epitaxial areas. There is risk of failure. Thermal stress or relatively mild abrasion may part the interface and cause the unanchored areas to blister. Adhesion is improved by postplating annealing. The oxide at the interface is dissolved in one or other metal, or diffuses to grain boundaries and alloying at the interface produces the desired metallic bond.

Pseudomorphism has less desirable consequences, and usually means are sought to suppress it. If the substrate has been scratched, ground, or abrasively polished, or if it has been cold rolled or cold formed, the surface is left in a peculiar state. Cold working reduces the surface grain size, and produces deformed, shattered, and partly reoriented metal. It may produce microcrevices between the deformed grains, and, with some processes, nonmetallic impurities and oxides are embedded in the surface. The disturbed state of the substrate is copied by a pseudomorphic electrodeposit with several consequences (Figure 7). One is aesthetic, as it has often been noted that almost invisible abrasion of the substrate develops, as more prominent markings in the

deposit. A chalk mark on steel produces local abrasion, hardly noticeable when the chalk is wiped away. If a strongly pseudomorphic electrodeposit is applied, the chalk mark reappears indelibly on its surface. A bright deposit may have its luster greatly reduced by pseudomorphic growth on a deformed surface (Figure 8). The corrosion protection is reduced if pseudomorphism with a deformed substrate leads to discontinuities at ill-fitting deposit grains (Figure 9). A pseudomorphic coating usually presents a dull or rough crystalline appearance. When the crystal form of the substrate is copied in the deposit, growth generates faces of simple index. An artificial face of high index soon grows out when plated. Tradition demands a featureless mirror surface on metal coatings, and a way of producing this, which has attracted much commercial effort, is by using brightening addition agents. Microsections of electrodeposits from the more effective bright plating

**Figure 7** The disturbed structure of a scratch, with fragmented and distorted grains, is perpetuated by a strongly pseudomorphic electrodeposit.

**Figure 8** A fairly strongly pseudomorphic bright tin deposit (left) has its brightness impaired by the shattered surface layer produced on steel by cold rolling. When this layer is removed, the deposit is mirror bright (right). Coating 5 mm thick.

baths do not exhibit pseudomorphism. The deposit usually shows no grain structure, but instead a series of light and dark grain bands parallel to the substrate (Figure 10). Pseudomorphism is suppressed by the addition agent adsorbing on, and blocking areas taking part in, pseudomorphic growth. In the initial stages of bright plating, the addition agents adsorb at similar points on the substrate. Growth commences from fewer substrate nuclei when annealed nickel is plated in a bright nickel bath than in a dull (Watts') bath without additions. In the earliest stages of deposition, replicas of the surface show evidence of pseudomorphism even in bright baths (the substrate grain boundaries are carried into the deposit) but this is suppressed rapidly as the thickness increases. The aim with bright plating baths is to inhibit growth sufficiently to suppress pseudomorphism, but not so much as to suppress epitaxy and adhesion. An excessive concentration of addition agent will also suppress epitaxy, so that deposition occurs on to an adsorbed layer of brightener. Brightener adsorption is often potential dependent and trouble may occur first at high current density (low potential) areas.<sup>58-64</sup>

#### 4.07.6.7.2 Electrolyte effects

As a deposit becomes thicker, the influence of the substrate diminishes, and eventually the structure is characteristic only of the electrolyte composition, the temperature, current density, and mode of agitation. A great variety of structures are observed; some are analogous to those seen in cast metals, but others are obtained only by electrodeposition. Crystalline deposits

**Figure 9** Corrosion resistance of tin–nickel electrodeposit impaired by pseudomorphic porosity originating on cold-rolled steel surface (left). Panel on right has had the shattered grain surface removed by chemical polishing (0.125 mm removed). Coating thickness 15 mm; panels exposed 6 months to marine atmospheric corrosion (Hayling Island).

**Figure 10** Banding often observed in microsections of bright electrodeposits. (a) Bright tin (courtesy of the Tin Research Institute), and (b) and (c) bright gold.

from baths containing little or no addition agent often develop a preferred orientation texture. Some bright deposits show a texture, but in general as growth processes are progressively inhibited by increasing addition agent concentration or by using more active materials, the deposit becomes progressively finer grained and loses preferred orientation textures.

The compositions of baths, chosen for practical use, result in initial rates of lateral growth much greater than the rate of outward growth. This is a desirable feature; it causes the coating to become continuous at low thicknesses. The opposite condition of a faster rate of outward growth is undesirable, and results in a noncoherent deposit. Predominantly, outward growth occurs when the transport of metal ions becomes slow compared to their rate of discharge, that is, it is favored by high current density, low temperature, and lack of agitation. Lateral

growth processes are then starved of material to support them, but outward growth moves the deposit towards the supply, and the prominences formed benefit from greater diffusive flux. There are strong pressures in industrial production to increase electroplating rates, which carries a danger of using high current density and causing a shift to outward growth. In baths where the coating is electroplated from aquocations at high cathode efficiency, the onset of lateral growth is fairly sharp. Cathodes have a range of local current density, and the coating on the high current density areas becomes friable, dark colored, and rough as the transition is reached. Such coatings are termed 'burnt' and the corrosion protection is degraded. With baths working in the acid pH range, there is the complication that once an appreciable part of the current is used to reduce water, the pH at the cathode rises and insoluble hydroxides are precipitated and incorporated in the coating. With complex cyanide baths, the onset of 'burning' is less sharp. There is normally considerable simultaneous hydrogen discharge, and as the current density rises, there is no sharp limiting current density for metal discharge. Addition agents raise the lateral-outward transition to higher current densities by inhibiting outward growth. Nevertheless, all electroplated coatings show signs of deteriorating properties if the baths in which they are produced are worked at sufficiently high current density.<sup>66-70</sup>

#### **4.07.6.7.3 Form of current passed through cell**

Commercial electroplating began with pure DC from galvanic cells. Later, for many years, DC generators were used. Their current output is unidirectional but with a superimposed ripple. Part of the ripple stems from the angular motion of the armature coils during the period they supply current to a commutator segment and part from variations of contact resistance at the commutator. Generators have been superseded by transformers and rectifiers. Copper-oxide, mercury-arc, selenium, germanium, and silicon rectifiers have been used and examples of each are to be found in service. These devices supply varying unidirectional current whose form depends on the number of phases in the input and the circuit used. A half-wave single-phase rectifier provides a pulsating current; a full-wave three-phase set has a much smoother output.

Alternating currents with asymmetric forms have been used, mainly for electroforming and thick engineering deposits. Where the cycles are slow,

for example, several seconds, the term periodic reverse current (p-r-c) is used. The benefit claimed for p-r-c plating is that smoother, thick deposits result from selective dissolution of peaks in the reverse part of the cycle. This assumes the electrode process reverses during the anodic period, which is not always the case. In chromium plating, the coating becomes passive in anodic periods, while in acid gold baths based on aurocyanide, the process is also irreversible. More recently, asymmetric AC with a much higher frequency of 500 Hz was found to alter beneficially the properties of nickel from chloride baths.

Pulses of unidirectional current have been used to modify coating properties. When plating starts, it is possible, for a time, to use a current much higher than the steady-state limit, drawing on the stock of ions near the cathode. Provided sufficient time is allowed between pulses, a coating can be built of layers plated at much higher current density than normal. Improved gold coatings were produced by relatively rapid pulses. The technique of barrel plating results in pulse plating of an irregular sort, with pulse durations of the order of seconds and inactive periods rather longer.

Chromium plating from chromic acid baths is more sensitive to the source of current than most other processes, sufficiently so for commercial operators to use at least three-phase rectifiers as a rule, and to take precautions against any temporary break of current during voltage regulation. A recent investigation showed that the ripple introduced by thyristor control of rectifiers was detrimental to chromium electrodeposits.<sup>71-80</sup>

#### 4.07.6.8 Industrial Electroplating Techniques

Electroplating is usually a finishing technique applied after an article has been completely fabricated. Fairly large articles, from cutlery to motorcar bumpers, are dealt with by vat plating. They are suspended by a conducting connection in a rectangular tank or vat of electrolyte. The anodes are arranged about the periphery of the tank. For small runs the cathodes may be suspended by copper wire wrapped round a suitable part, but for longer runs a plating jig is used. This is a copper frame with phosphor bronze spring contacts to hold the work and insulated, usually with a PVC coating, on all but the contact points. The point of contact between wire or jig and the article becomes a weak part in the coating, and some thought should be given to providing or selecting contact points in insignificant areas.

Vat plating is used sometimes with articles too large for complete immersion. Printing, calendering, drying, and similar rolls are part-immersed and revolved continuously during plating. However, it is much more difficult to plate half an object, reverse it, and complete the other half later; the 'join' between the two deposits is rarely satisfactory.

Small objects, nuts, bolts, screws, and small electrical parts are plated in a revolving barrel. Electrical connection is made by a conductor immersed in the tumbling mass, and electrodeposition, which is confined to the outer layer of the mass at any instant, takes place in intermittent stages for any individual object. The coating is abraded during the process. The peculiarities of chromium deposition set it apart, and the normal barrel-plating processes are not used. In the so-called chromium barrels, the small parts travel and tumble along a helix inside a rotating cylinder during deposition, and are electroplated for a much greater proportion of the time than are parts in normal barrels.

Brush plating is a special technique which dispenses with a container and uses a swab soaked in electrolyte applied to the work. In jet plating, a stream of electrolyte is applied to the cathode. Both are methods of selective plating, applying an electrodeposit to only a part of an article. Little has been published about the techniques or the properties of coatings they produce.

Continuous plating of wire and strip is, unlike the preceding techniques, a prefabrication process. The production of tinplate is the largest scale continuous operation, but any electrodeposit may be applied this way. Subsequent fabrication processes are likely to damage the coating, so that precoating is best reserved for ductile coatings which are anodic to the substrate in service, as is the case for tin.<sup>81-83</sup>

#### 4.07.6.9 Rinsing

Between all stages of immersion (cleaning, pickling, plating, postplating treatment) work has to be rinsed. Once the hydrophobic solid has been removed, metal surfaces withdrawn from solutions carry a film of liquid. The solution lost this way is known as drag-out. A film 10 mm thick is the minimum retained by smooth, well drained, vertical surfaces. On rough or horizontal surfaces, and in recesses it is much thicker, as it is also with viscous solutions. During rinsing, the film is diluted, and the ratio of the final concentration to that present initially is the dilution ratio. The dilute material is carried forward to the next process,

and clearly the highest concentration of impurity permissible before the subsequent process is affected adversely determines the maximum dilution ratio that can be allowed. Sometimes there is a minimum dilution ratio; between nickel plating and chromium plating it is essential that the rinsed metal surface does not become passive, and prolonged rinsing carries a danger of eliminating the slight but important amount of rinse water corrosion which keeps the surface active between stages.

Usually rinsing troubles are caused by a dilution ratio that is too high. If incoming work passes through a process stage, and the drag-out from that stage is in turn discarded in a subsequent rinse, the maximum concentration of material carried into the bath is equal to that in the film carried over. However, there is an increasing tendency to conserve materials and steps are taken to return drag-out losses. In so doing, the impurities are also returned, so conservation measures require a reduction in the dilution ratio of the preceding rinse. Inadequate intermediate rinses are detrimental to the corrosion resistance of the coating because carried-over impurities impair the functioning of plating baths. Inadequate final rinsing leads to increased corrosion of the coating, and to staining. Staining, which is a serious aesthetic problem with decorative coatings, may itself arise from corrosion. Some stains are caused by the precipitation of dissolved solids when rinse water evaporates, but in other cases, they are caused by corrosion supported by the presence of an electrolyte in the rinse water.<sup>84-93</sup>

#### 4.07.6.10 Postplating Treatments

Where the corrosion resistance of a coating depends upon its passivity, it is common to follow plating with a conversion coating process to strengthen the passive film. Zinc, cadmium, and tin in particular are treated with chromate solutions which thicken their protective oxides and also incorporate in it complex chromates. There are many proprietary processes, especially for zinc and cadmium. Simple immersion processes are used for all three coatings, while electrolytic passivation is used on tinplate lines. Chromate immersion processes are known to benefit copper, brass, and silver electrodeposits, and electrolytic chromate treatments improve the performance of nickel and chromium coatings, but they are not used to the extent common for the three first named.

The tin coatings as deposited in tinplate manufacture are not bright. Until comparatively recently,

bright tin electrodeposition was not practiced commercially, there being no reliable addition agents. To produce bright tin on tinplate and other products, the process of flow melting or flow brightening is used; tinplate is heated by induction or resistance, and plated articles are heated by immersion in hot oil to melt the tin, which flows under surface tension to develop a bright surface. While the tin is molten it reacts to form an alloy layer with the substrate. The alloy layer alters the corrosion behavior.

Other electroplated articles are heated after plating to expel hydrogen which has entered the substrate during cleaning, pickling, and plating, and which embrittles some metals, mainly high-strength steels. Generally speaking, alteration of the deposit structure and properties is not desired. Another use of postplating heat treatment is to improve adhesion, as already mentioned (Section 4.07.6.7.1).

Mechanical polishing, formerly the principal means of producing bright coatings, has become less important with the extension of the use of brightening addition agents. Mechanical polishing reduces the thickness of a coating, and may cut through to the substrate. As corrosion resistance is related to thickness, mechanical polishing can be detrimental. It may also increase porosity.<sup>94-97</sup>

### 4.07.7 Properties of Electrodeposits

#### 4.07.7.1 Thickness

Coating thickness is one of the most important quantities connected with corrosion resistance, and its measurement and control are features common to all electroplating operations and in all quality specifications. In some cases, coating thickness has functional importance, for example, where there are fitting tolerances, as with screw threads. However, in most cases, it is the connection with corrosion resistance that makes thickness important. Where the coating is anodic to an area of substrate exposed at a discontinuity, the coating is slowly consumed by corrosion, but the criterion of failure is the appearance of substrate corrosion product. This does not form until almost all the coating is consumed. Coatings which are cathodic to the substrate must have no discontinuities if substrate corrosion is to be suppressed.

The criterion of failure is usually the same. Freedom from discontinuity is also related to thickness. Discontinuities have three origins: spontaneous cracking to relieve internal stress, pores formed during the growth of the coating, and abrasion and wear.

The last two causes, that is, porosity and wear, both exhibit diminishing incidences as thickness rises. Apart from the peculiar case of electrodeposited chromium, internal stress cracking is a sign of incorrect plating conditions. Broadly speaking, thickness and corrosion resistance increase together. The thickness of an electroplated coating is never uniform. On the significant area (i.e., that on which corrosion resistance and other special properties are important) of a plated surface, there are two important thicknesses, that is, (a) average thickness, which determines the production rate and plating costs; and (b) minimum local thickness, which, as the weakest link in the chain, determines the corrosion resistance. The ideal is to make these equal; the larger the difference the greater the waste of metal. The difference can be reduced by special procedures, but at a cost.

When the cathode is being plated, the electrical field is not uniform. Both electrodes are equipotential surfaces, so that prominent parts of the cathode, for example, corners, edges, protuberances, etc. which are relatively nearer to the anode are plated at a higher average current density, resulting in a thicker coating. Recesses and more distant parts are more thinly plated. Distribution of thickness tends to be the reverse of that found with paints, hot-dipped articles, and other coatings that are applied as liquids. Liquid-applied coatings are thin on sharp edges, and thick in recesses because of the effects of surface tension and radii of curvature.

The numerous factors which contribute to the thickness distribution can be divided into two groups, that is, (a) those connected with the nature of the plating bath (see below), and (b) those to do with the geometry of current paths in the bath, including the shapes of the electrodes. (Reference should be made to publications on electrodeposit specifications of the British Standards Institution, American Standards Institution and other standardizing bodies.)

#### 4.07.7.2 Throwing Power

In a given plating cell, thickness distribution is found to vary with bath composition, current density, temperature, and agitation. It is common to speak of the throwing power of a plating bath. The throwing power of chromic acid baths is poor, that is, there is a relatively large difference between maximum and minimum local thickness; conversely, the throwing power of alkaline stannate baths is good, that is, there is much less difference in the local thicknesses.

Strictly speaking, the bath composition should be qualified by the conditions of use, as they affect throwing power. Otherwise, the usual conditions are implied. A numerical throwing index can be calculated from the performance of a plating bath in a cell of standard geometry. Two widely used cells are, (a) the Haring–Blum cell, and (b) the Hull cell (Figure 11). The Haring–Blum cell was devised for throwing index measurement; the Hull cell is used mainly to study the effects of varying bath composition.

The Haring–Blum cathode is divided into two equal plane areas, distant  $l_1$  and  $l_2$  from a common anode, and a quantity called the primary current density ratio  $P$  is defined as

$$P = l_2/l_1$$

This is the ratio in which the current would divide, if electrolytic resistance were to control its flow entirely. The metal distribution ratio  $M$  is the ratio of the thicknesses of the coating actually deposited during a measurement. There are several numerical scales of throwing index  $T$ , but Field's is widely adopted:

$$T = 100 \frac{P - M}{P + M - 2} \% \quad [11]$$

On this scale, zero represents the case when  $M = P$ , and electrolyte resistance is the main factor. Throwing power can be worse, down to a limit  $T = -100\%$  when  $M = \infty$ , that is, no deposit at all on the far cathode. Conversely, when  $M < P$ ,  $T$  is positive, where  $M$  to reach 1.0 despite the difference in position,  $T = +100\%$ . At one time,  $+100\%$  was regarded as an unrealizable limit, but conditions have been found for which  $T = +150\%$  in a Haring–Blum cell equation.

The Hull cell cathode has a continuous variation of current density along its length, and there are

**Figure 11** (a) Haring–Blum cell for throwing index measurement, in elevation and (b) Hull cell (plan view) which can also be used for measuring throwing indices.

equations which give the primary current density at any point not too near the end. If the local thickness is measured at two points for which  $P$  is known,  $T$  can be calculated. The real current distribution is a function of cathode and anode polarization as well as of the resistance of the electrolyte. The metal distribution ratio will be

$$M = \frac{(V - \Delta E_1)}{(V - \Delta E_2)} \times \frac{l_2}{l_1} \times \frac{\varepsilon_1}{\varepsilon_2} \quad [12]$$

where  $V$  is the cell potential difference between anode and cathode,  $\Delta E$  is the total potential difference caused by polarization (anode and cathode) on the cathode area indicated by the subscript, and  $\varepsilon$  is the cathode efficiency as indicated by the subscript.

As  $\Delta E$  will be a function of current density,  $T$  will be a function of electrode area, and comparisons should, therefore, be made with cells of standard size. Equation [12] shows that high throwing indices will result when polarization rises steeply with current ( $\Delta E_1/\Delta E_2$ ) and cathode efficiency falls steeply ( $\varepsilon_2/\varepsilon_1$ ). The primary current ratio,  $P = l_2/l_1$ , affects the result because by altering the currents the polarization terms are altered. For example, with an acid copper bath in a Haring–Blum cell,  $194 \text{ A m}^{-2}$  average CD:

$P$	2	5	11	23
$T$ (%)	+7	+11	+22	+41

An increase in conductivity usually increases  $T$  because it increases the proportion of polarization in the total cell potential difference and lowers the ratio  $(V - \Delta E_1)/(V - \Delta E_2)$ . Changing the conductivity, an acid copper bath with sulfuric acid produced the following result ( $291 \text{ A m}^{-2}$  average CD,  $P = 5$ ):

Conductivity ( $\text{S cm}^{-1}$ )	0.08	0.15	0.26	0.30
$T$ (%)	+5	+11	+13	+27

where S is the SI unit of conductance (Siemens).

Many baths in which metal is reduced from complex anions (e.g., cyanide baths, stannate baths) give high throwing indices because both polarization and cathode efficiency variation favor a low value of  $M$ . The cathode efficiency for a typical copper cyanide bath ( $40^\circ\text{C}$ ) was

Cathode current density ( $\text{A m}^{-2}$ )	199	253	384	763	1785	5130	30800
Cathode efficiency (%)	0	5.9	11.9	13.9	18.8	22.7	24.4

The throwing index for the cyanide bath is usually about +40% and rises as the cell current is increased to as high as +85%. Aquocation baths give values near  $T = 0$ , though conditions may be selected which give much higher figures if there is a steeply rising section of the polarization curve. Chromium plating baths invariably have large negative throwing indices, despite deposition from a complex ion. The cause is the anomalous rising trend of cathode efficiency with current density and the existence of a minimum current density below which the efficiency is zero. A typical bath ( $400 \text{ g l}^{-1} \text{ CrO}_3$ ,  $4 \text{ g l}^{-1} \text{ H}_2\text{SO}_4$ ,  $38^\circ\text{C}$ ) gave the following data:

Current density ( $\text{A m}^{-2}$ )	32	65	129	258	388
Cathode efficiency	76	68	56	34	21

If the current density on the far cathode in a Haring–Blum cell was  $199 \text{ A m}^{-2}$  or less,  $T = -100\%$ .

Throwing indices measured in a Hull cell differ from those in a Haring–Blum cell because of the differences in geometry. In a Hull cell, several pairs of points can be found, which have the same primary current ratio, but for which  $M$  and hence  $T$  are found to vary because of polarization changes.<sup>98–105</sup>

#### 4.07.7.3 Current Path Geometry

The polarization and cathode efficiency terms in eqn [12] cannot be altered in practice to improve thickness distribution, as they tend to be decided by overriding considerations. It is usual to accept the distribution obtained without special precautions as being the best commercial solution, although the average thickness needed to achieve the necessary minimum local thickness may be high. Where this approach does not serve, there are a number of methods of altering the term  $l_2/l_1$  in eqn [12]:

- By using shaped (conforming) anodes, additional (auxiliary) anodes or ‘bipolar’ anodes to bring anode areas nearer to cathode recesses. Insoluble anodes are better where they are applicable, as they do not alter the original shape during use.

- (b) By using nonconducting shields of plastic or glass to equalize the current path lengths.
- (c) By placing auxiliary cathodes ('robbers' or 'thieves') near high-current-density points to divert deposition. This does not save metal, but has the merit that auxiliary cathodes can be incorporated into jigs for long runs in automatic plating machines. Auxiliary cathodes are used in heavy chromium deposition, where metal waste is secondary to the cost of removing excess chromium when grinding to precise dimensions. Where a number of small parts are plated together on a jig, it is usually possible to dispose them so that they serve as 'robbers' for each other.
- (d) By paying attention to certain 'rules' when designing articles which will be finished by electroplating. Many external contours are chosen for reasons of style. It helps to avoid features like sharp recesses, which are bound to cause trouble. A simple rule is the '1 in ball test' or perhaps the '25 mm ball test': if there is any part of a surface which a ball of this diameter cannot touch when rolled over it, there will be difficulties. There are other design aspects, covered in specialist publications, attention to which improves the corrosion resistance, which can be imparted by plating.<sup>106-110</sup>

#### 4.07.7.4 Structure-Dependent Properties

##### 4.07.7.4.1 Composition of the electrodeposit

Attention has been drawn to the dependence of structure on both substrate and plating conditions, and to the transition in properties which occurs across the section of a deposit. Most commercial electrodeposits have a high purity, yet in a sense impurities are vital to their successful application. Alloy electrodeposition possesses the literature whose bulk attests the subject's fascination for research (which the authors share), but is out of proportion to the extremely limited commercial applications. Alloys in general metallurgical practice provide a variety of mechanical properties; in electroplating the range of properties desired is narrower, and it can generally be achieved by altering the structure of a single metal deposit through changes in the plating bath composition or plating conditions. The microstructure of an electrodeposit can be altered much more than that of a cast and worked metal. This is because the deposit forms well below its melting point, where crystallization processes are hindered by the virtual absence of

solid-state diffusion. Consequently, very small amounts of 'impurity' absorbed at important growth sites on the surface cause large changes in the structure of what is, chemically, almost pure metal. The structure is metastable, but permanent as long as the electrodeposit is not heated. A variety of mechanical and physical properties are a reflection of the structure: hardness, ductility, tensile strength, internal stress, electrical and thermal conductivity, etc. As the structure of an electrodeposited metal is altered by changing the plating conditions, the mechanical and physical properties also alter. A plot of structure-dependent properties against the plating variable usually shows the various properties moving in parallel or inverse motion, and over ranges not accessible in cast and worked metal of the same composition. However, if electrodeposits are heated to temperatures where moderate mobility of the atoms is possible, their properties rapidly revert to 'normal.' The corrosion resistance of electrodeposits depends much more on chemical composition than on structure, so that the corrosion resistance of a particular metal is retained for a wide range of mechanical and physical properties.

The 'impurities' responsible for modifying the structure may originate from water (dispersed oxides); adsorbing ions, especially cyanides; organic addition agents parts of which are incorporated; or ions of a second metal which are codeposited. Some regard deposits in which the impurity is a small amount of a second metal as an alloy, but generally, they have the same sort of metastable structures as are obtained with nonmetallic impurities, rather than the structures of stable alloys of the same composition. The 'alloying' metal serves to cause and perpetuate a nonequilibrium structure whose real basis is the low temperature of the electrocrystallization process. Generally, the corrosion properties of the various different structures of a given metal are much the same, with the notable exception of nickel containing sulfur from addition agents, which has already been mentioned.<sup>111-116</sup>

##### 4.07.7.5 Internal Stress

Electrodeposits are usually in a state of internal stress. Two types of stress are recognized. First order, or macrostress, is manifest when the deposit as a whole would, when released from the substrate, either contract (tensile stress) or expand (compressive stress) (**Figure 12**). Second order, or microstress, occurs when individual grains or localities in the

metal are stressed, but the signs and directions of the microstresses cancel on the larger scale. The effects of first-order stress are easily observed by a variety of techniques.

Second-order stress is difficult to observe and much less extensively studied. The causes of internal stress are still a matter for investigation. There are broad generalizations, for example, 'frozen-in excess surface energy,' 'a combination of edge dislocations of similar orientation,' and more detailed mechanisms advanced to explain specific examples.

Tensile first-order stress is a corrosion hazard in coatings cathodic to the substrate. Compressive stress is not usually troublesome, nor is the stress of either sign in anodic coatings. Less can be said about high

second-order stress, though it may well cause brittleness. If tensile stress is large enough, the coating cracks and a cathodic coating will fail to protect, as illustrated in **Figure 13**. Tensile stress below the level needed for spontaneous cracking lowers the fatigue limit of a substrate. Tensile stress can in several cases be reduced to safe values by fairly minor changes in microstructure and plating conditions, insufficient to upset other desirable properties. Saccharin is an addition agent for reducing stress in nickel; additions of ammonium chloride reduce stress in tin–nickel alloy; and small changes in bath temperature and  $\text{CrO}_3\text{:H}_2\text{SO}_4$  ratio reduce stress in chromium.

The effects of tensile stress in the various layers of nickel plus chromium coatings are complex, and internal stress in both chromium and nickel (post-nickel strike or PNS) layers can be harnessed to produce beneficial cracking ('microcracking')<sup>117–120</sup>.

#### 4.07.7.6 Ductility, Hardness, Wear, Strength

The mechanical properties reflect very closely the structures of electrodeposits. The softest, most ductile, weakest form of a particular metal is that with a large crystal size, deposited with minimum polarization from baths, which have no addition agents. This is the type of deposit in which pseudomorphism is strongest. In terms of the accepted deposition mechanism, there is the least inhibition of adion mobility as the deposit grows, and least inhibition of those sites at which equilibrium growth would occur. This electrodeposit has properties the nearest to those for the annealed metal, but even so tends to be somewhat harder. Because of pseudomorphism the properties near the substrate interface may be greatly modified if the latter has a metastable structure, especially one

**Figure 12** An electrodeposit showing unusually high compressive stress. A 150 × 150 mm copper sheet was insulated with lacquer on one side and electroplated with Sn-35 Ni alloy. The high compressive stress has caused the sheet, originally flat, to coil in the manner shown, with the electrodeposit outside.

**Figure 13** Cracking in a cathodic coating due to a tensile stress that exceeds the cracking strength, leading to loss of protection. All 5  $\mu\text{m}$  coatings of Sn–Ni alloy on steel. From left to right, values of stress in  $\text{N mm}^{-2}$ : 134 tensile, 86 tensile, 57 tensile, and 127 compressive.

with very small grains produced by mechanical working. The deposit in turn becomes 'work hardened' by pseudomorphous growth.

When electrodeposition is inhibited, the metal becomes harder and less ductile, and tensile strength is increased. Metals deposited from acidic solutions of aquocations become harder when the pH is raised to near the value at which the hydroxide precipitates. Codeposited oxide acts as an addition agent, giving small-grained, hard deposits. Hard nickel is produced for engineering surfacing from high-pH baths. Many metals can be electrodeposited in extremely hard forms from inhibited baths, but they tend to become brittle, with high internal stress, so that the true tensile strength is hard to establish. Ductility necessarily falls as hardness rises, and coatings become more susceptible to damage by impact, reducing their protective value if they are cathodic to the substrate. Some applications of electroplating depend on the production of unusually hard and wear-resistant forms of corrosion-resistant metals. Thick coatings of chromium and nickel are applied to numerous steel parts to combine wear resistance with corrosion resistance. Thick or engineering chromium electrodeposits crack repeatedly during deposition, but the cracks are subsequently sealed and none should traverse the entire coating. Thick chromium coatings have practically no ductility, and because of their defective structure they have a low effective strength. They serve best on stiff substrates.

Gold coatings on separable electric contacts and slip rings make use of the high hardness possible with electrodeposition to resist wear. Rhodium is another metal which can be exceptionally hard. Thick coatings have a cracked-sealed structure similar to that of chromium.<sup>121-124</sup>

#### 4.07.7.7 Interdiffusion with the Substrate

A thin metal coating on a metal substrate is not a stable entity; greater stability would be attained if the coating were to diffuse evenly throughout the substrate. Fortunately, at ambient temperatures most of the usual combinations interdiffuse sufficiently slowly to present no practical problem. At high temperatures, however, many coatings diffuse quickly. Diffusion in a few systems at moderate temperatures causes corrosion problems. Difficulties can occur with tin, which, with its low melting point of 231 °C, is relatively 'hot' at room temperature. On copper and copper-alloy substrates, diffusion transforms the tin into the intermetallic phases  $\text{Cu}_6\text{Sn}_5$

and  $\text{Cu}_3\text{Sn}$ . At 100 °C, the transformation is accelerated, and 5 mm of tin may become wholly alloyed within a year. The alloy coating may pass as tin having a silvery color, but it is much harder and has a very stable passivity. One use of tin on copper is to facilitate easy joining by soldering, but the alloy has a high melting point and is not easily wet by solder. Thin 'tin' coatings on copper which have become wholly alloyed in storage are difficult to solder. Sometimes extremely thin coatings (0.25 mm) used purely for solderability become wholly alloyed in a few weeks. Parts should not be stored too long and very thin coatings are a false economy.

Tin will protect copper from corrosion by neutral water. Pure tin is anodic to copper, and protects discontinuities by sacrificial corrosion. Both intermetallic phases are strongly cathodic to copper and corrosion is stimulated at gaps in wholly alloyed coatings. An adequate thickness of tin is needed for long service, for example, 25–50 mm. Another diffusion problem occurs with tin-plated brass. Zinc passes very quickly to the tin surface, where under conditions of damp storage zinc corrosion products produce a film which greatly impairs solderability. An underplate of copper, or better still nickel, usually cures this trouble.

A similar problem, that is, diffusion of the substrate through the coating to corrode at the surface, arises with gold-plated copper. Many gold coatings are used to ensure a low electric contact in electrical connectors. Gold is preeminent because of the absence of stable-corrosion-product films under most service conditions, but it is expensive, so coatings are kept as thin as possible. Electronic devices may operate at fairly high temperatures (100–150 °C), and significant amounts of copper may diffuse through the coating to produce a film of oxide on the surface, nullifying the contact value of the gold. Nickel underplate mitigates this trouble (though increasing plating difficulties). To reduce costs, attempts have been made to dilute gold with cheaper metals, while retaining gold-like corrosion properties. Cadmium has been used as a diluent, but while quite high cadmium-golds are gold-like at 25 °C, at higher temperatures, cadmium gets oxidized at the surface. Pure gold is preferred for high temperature contacts.<sup>125,126</sup>

#### 4.07.7.8 Porosity

In the very earliest stages of electroplating, the substrate carries discontinuous areas of deposit growing around nuclei. Lateral growth causes the great

majority of growing edges to coalesce with sufficient perfection to be impervious to corrosive gases and liquids. On normal metallic substrates, a few edges do not grow together, and a gap remains in the coating. As the coating thickens, the gap is propagated as a channel through the coating, to form a pore. Under the conditions chosen for practical electroplating, pores diminish in cross section as deposition continues, and pore density (pores per unit area) falls as thickness increases. The corrosion which occurs when pores allow liquid and gaseous corrosive agents to reach the substrate varies in importance according to the relation between the corrosion potentials of deposit and substrate, the corrosive environment, and the function of the coating.

If the environment favors wet corrosion processes, relative polarity is the main consideration. If the coating is anodic, porosity is seldom of any serious consequence. The cathode is the very small area of substrate exposed at the base of the pore, and the restricted channel limits the diffusion of reactants and products. The large anode area provided by the coating reduces the bimetallic corrosion current density thereon. Two important examples of this type are zinc coatings on steel in cold waters or the atmosphere and tin coatings on steel on the inside (but not the outside) of a sealed, air-free can of wet food. In the first case, oxygen is the cathodic reactant; in the second it is hydrogen ions (or water). Where the coating is cathodic, porosity enables the exposed substrate to corrode. In most cases, this is detrimental; the exception is found in some multi-layer nickel plus chromium coatings where certain forms of porosity in the chromium layer are harnessed to divert the direction of corrosion to the overall benefit of coating life. In other cases, corrosion at pores causes trouble. In wet atmospheric corrosion, substrate corrosion product, if colored and insoluble, spoils decorative appearance. In immersed conditions or humid atmospheres, if the corrosion product is soluble, intense pore corrosion will perforate sheet metals. Here, a porous coating may accelerate corrosion when compared to the uncoated substrate.

Porosity causes little trouble when corrosion is restricted to dry processes (oxidation). Corrosion products block the pores and stifle the reaction.

There was much research into the causes of porosity in nickel deposits when it was thought to be the main cause of failure in nickel and chromium plates. Much was discounted as it became clear that nickel pitting at discontinuities in the chromium was the factor determining service life. Porosity remains

relevant to the corrosion resistance of simpler cathodic coatings, and especially for gold. The use of gold for contact surfacing since around 1950 has revived the importance of studies of porosity. Pores in gold coatings allow films of substrate corrosion product to contaminate the surface and to destroy the low contact resistance of the gold. Sulfides, which are one of the products of corrosion by service atmospheres, have a particularly high rate of spreading over gold in the solid state (**Figure 14**).

Pores originate on substrate areas known as precursors, which are of at least three types. Firstly, an obvious cause is an inclusion of foreign material which is a semiconductor or insulator – particles of oxide, sulfide, slag, polishing abrasive, etc. When electrodeposition starts, inclusions will not be nucleation sites, and they will impede the lateral growth and coalescence of crystals from neighboring nuclei. Secondly, substrates whose surface grain structure has been severely disturbed by cold working (abrasion, cold rolling, drawing, etc.) have precursors whose physical state (rather than chemical difference as in the first type) precludes coalescence of the electrodeposit. This is probably an effect of pseudomorphic growth. Relatively low-temperature annealing (as low as 210 °C for steel) greatly reduces the effect, and further cold work increases it again (**Figure 15**). The third type of precursor is a crevice in the substrate. If the depth is great relative to the width, the electric field is excluded and deposition does not occur within the crevice. Lateral growth is impeded once the edges from neighboring nuclei reach it in much the same way as with a nonconducting inclusion. A pore caused by any type of precursor in one

**Figure 14** Spread of silver sulphide from discontinuities in gold electrodeposits on silver substrates. The gold was deliberately scratched and the specimen exposed for 24 h to an atmosphere containing 10% SO<sub>2</sub>. Immediately after this the sulphide stain extended 0.2 mm. Five years later, the stain extends to about 13 mm, after storage in a normal indoor atmosphere.

**Figure 15** Porosity caused by a cold-worked substrate. Left (EQE 76) cold-rolled steel as received; centre (EDE 52) steel bright-annealed in vacuum before plating, 2.5 h at 700 °C; right, annealed steel, further cold-rolled (0.914 mm to 0.864 mm) produces porosity again. No steel was removed from the surface; 5 mm tin-nickel electrodeposit.

electrodeposit becomes in turn a precursor for a second deposit plated over it. There may be other forms of precursor.

In a particular area of substrate, there will be a number of precursors, distributed over a range of sizes, and reflecting the nature, composition, and history of the metal. In principle, anything affecting the substrate surface will affect porosity in an electroplated coating.

As deposition continues, growth gradually diminishes the surface opening of a pore and, if continued to a sufficient thickness, closes it, leaving a sealed cavity filled with solution. Small precursors will generate pores which seal relatively early, large ones will require greater thicknesses. The total pore density, revealed by a test which renders pore sites visible, falls as thickness increases. The minimum thickness required to seal a precursor of fixed size will depend on the rate of narrowing of the surface opening, and as a growth process, this will reflect the plating conditions. Because of this, the density of pores still open at a fixed thickness is a function of all the plating conditions, that is, the composition of the plating bath, temperature, current density, agitation, and anything affecting deposit growth.

Postplating treatments affect pore density, either by closing pores which are still open or opening sealed ones. It has been asserted that mechanical polishing in general and flow-melting for tin are both processes which could seal pores and reduce porosity. It is also conceivable that polishing might cut-open sealed pores, and likewise under flow-melting conditions, the vaporization of solution trapped in sealed pores could disrupt the coating and recreate discontinuities. The author has come across no convincing demonstration of porosity reduction by either treatment, but has found experimental evidence for porosity increases (**Figure 16**).<sup>127–139</sup>

**Figure 16** Increase in porosity of an electrodeposit caused by mechanical polishing. Left, 7.5 mm unpolished coating; right, polished with lime finishing compound. The average thickness removed by abrasion was 0.1 mm.

#### 4.07.8 Plating from Ionic Liquids

At first, this concept seems to be obvious and indeed the name is not well chosen. It relates to essentially nonaqueous solutions which are conducting and ionic, a field that was formerly referred to as organic or nonaqueous plating. None of these titles are entirely satisfactory.

The need arises from several difficulties with conventional processes:

- The reactive base metals (e.g., Al, Mg, Ti) cannot be deposited from aqueous solutions.
- If the base metals can be deposited, inevitably the current efficiency is poor (e.g., Cr).
- If the substrate is steel, the inefficient production of hydrogen may be disastrous for its mechanical properties.

In the 1960s, the driving force lays with aluminum on the basis that aluminum-coated steel was an ideal combination for many corrosion needs; hot-dipped coatings were limited to thicknesses over  $\sim 20\ \mu\text{m}$ . A number of solvents based on alcohols, ethers, and ketones were used which gave poor results with major fire hazards; processes by Philips and Siemens had much publicity but no commercial success. Since 1990, alternative organic solvents based on low melting point ( $<100\ ^\circ\text{C}$ ) eutectic mixtures have been explored; the eutectic is formed from a metal complex salt such as borofluoride, phosphofluoride, or thicyanate and a methyl or ethyl imidazolinium, pyridinium, or quaternary ammonium (choline) salt. The requirement is that the mixture should be highly

conductive, have low viscosity, high metal solubility, and no propensity to absorb water.<sup>140,141</sup>

Research progress has been fairly rapid and all the common metals have been studied with especial concentration on Al, Cr, and Zn and its alloys. The possibility of electroless deposition has also been considered. No commercial operation has been reported yet, probably because while the cathode efficiencies are high, the practical current densities are still rather low: a report on an EU project *IONMET* has stated the challenges succinctly. However, the field must be considered promising for future development.<sup>140–143</sup>

#### 4.07.9 Recent Developments

Although the basic principles of electroplating remain unchanged, the extent of development and variety of application have widened substantially.<sup>144</sup> In this section, some notable developments will be cited.

The development of new solutions and processes continues unabated, driven, as ever, by commercial and proprietorial needs as well as pressure from pollution and effluent control demands and simply for the need to supersede some less-than-satisfactory solutions. Noncyanide solutions are continually being sought for metals such as gold, copper, cadmium, and zinc, but cyanide remains preeminent as the most effective and best understood complexant available and few competitors have been discovered. The other ecological *bête-noire* is hexavalent chromium, and several commercial bodies offer nontoxic trivalent chromium plating solutions, both aqueous- and organic-based, although only the former is believed to be industrially viable. The solutions are on the basis of chromic sulphate or chloride salts, a complexant such as hypophosphite, glycollate, thiocyanate, etc. and a depolarizing anode reactant which could include ammonium ions or a separated anode compartment. The cathode efficiency is still below 50% and only thin coatings can be reproducibly produced (10  $\mu\text{m}$  max.), but pollution difficulties are largely eliminated. This has proved to be a difficult area, but the number of successes is expected to increase.<sup>145–148</sup>

A separate problem is the establishment of a good process for electroplating aluminum which must necessarily be on the basis of a nonaqueous electrolyte. This field is a history of many discoveries, but few developed processes have been claimed, although recent work suggests that at least two good

possibilities exist which may make inroads in the electronics field rather than in the other important area of wide steel strip aluminizing.<sup>149,150</sup>

In his classic treatise, Brenner<sup>2</sup> reported that over 500 alloy electrodeposition systems had then been studied in depth – that number has now been substantially increased – yet barely 10–20 have any real degree of industrial exploitation. The list continues to grow and the present type of work on alloys can be divided into three classes:

1. The development of new alloys in new fields; for example the development of alloys of molybdenum and tungsten with iron, cobalt, or nickel for coating of dies and nozzles, or the development of palladium–nickel alloy as an alternative to gold for connectors.
2. The development of new alloys as a means of modifying existing electrodeposits; for example the production of hard gold alloy by codeposition of copper, cadmium, etc., to yield 23 or 18 carat alloys, or the use of zinc alloys for improved electrogalvanized coatings.
3. The development of new solutions for established alloys; for example, the replacement of fluoborate for lead–zinc brasses.

With industry proving to be so conservative about binary alloys, it is hardly surprising that ternary alloys receive little attention. Nevertheless, two ternary alloys at least have become commercially available: iron–chromium–nickel (so-called stainless steel) for both functional and domestic markets and an electronic connector and solderable alloy based on copper–zinc–tin.

The field of composite materials has been the major growth area of materials engineering in the last twenty years, based mainly on ceramic and polymer materials. While electroplated (and electroless) composites show more modest growth, this is attributable to the necessary limitation of metal matrices. Thus, the principle is to take a well established metal deposition process (gold, cobalt, copper, nickel, tin) and to induce codeposition of second-phase particles, thereby, enhancing coating properties such as hardness, wear, and oxidation resistance. The key to successful codeposition is having particles of appropriate size and density, typically 0.1–10  $\mu\text{m}$  size, suitably suspended in solution by a nonswirling agitation technique, that is, codeposition occurring by physical entrapment or electrophoretic attraction. Such particles include oxides (e.g.,  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ ,  $\text{ZrO}_2$ , etc.) or refractory hard compounds (e.g.,  $\text{Cr}_7\text{C}_3$ , WC,  $\text{Mo}_2\text{C}$ , etc.), abrasives such as diamond, lubricants such as  $\text{MoS}_2$  or graphite, and low-friction material

such as PTFE. A substantial literature exists, relating to both process and product characteristics and reference should be made to two notable reviews.<sup>151,152</sup> Several obvious applications have, to a large extent, been achieved; for example, second-phase hardening by  $\text{Al}_2\text{O}_3$  of gold without serious loss of electrical conductivity, high temperature erosion or wear resistance of nickel, nickel–cobalt gas turbine, or jet engine alloys improved by using carbide incorporation, and improved surface lubrication of nickel by incorporation of PTFE particles.

The use of current or voltage pulsing during electroplating has long been known to have a beneficial effect on the deposition process rate and on the deposit itself in terms of grain-size variation, internal stress, leveling, etc. Periodic reverse techniques (cycle time of 10–102 s) are widely employed in electrowinning and electrefining operations while pulse plating (cycle time of  $10^{-3}$  to 1 s), which requires more sophisticated electronics, is now of considerable interest for metal finishing. The basic theory has been discussed by Ibl<sup>153</sup> who has defined the parameters involved. Claims for improved brightening, leveling and throwing power are of especial interest in electronics but are not yet fully substantiated in many instances.<sup>154</sup> The cooperation of industrial and engineering designers with the metal finishers, who are frequently required to perform the near-impossible as a consequence of poor communication, is notoriously bad, largely as a consequence of the nature of subcontract industrial relationships. To meet this need, an important new standard – BS 4479 – has been issued; although it is ostensibly a revision of the old standard, it is in reality a new standard written essentially as a code of practice. Invaluable advice is given to finishers and designers alike: the challenge now is to have it widely read and appreciated!

Increasing awareness of the cost-effectiveness of electroplating processes has led to critical appraisals being made of cell design, not only to improve the product through improved efficiency and economics of the process itself, but also typically through the costs of electricity. Thus the use of more conductive solutions, combined with minimization of the anode–cathode spacing can yield a 40% saving in electrical power. However, not all of this saving is necessarily desirable if chemical costs, thereby, increase and the peripheral cost of solution heating has also to be increased. Similarly, improved agitation and filtration may also be considered for optimization studies. This ‘chemical engineering’ approach has found increasing value,<sup>155–159</sup> not least in the development of new types

of plating cell specifically for metal recovery from trade effluent, dragouts, and rinses.<sup>160–162</sup> In fact, the number of new designs far outnumbers the number of optimizing and independent assessment studies so that it is not possible to name a ‘best-buy,’ and time is needed for commercial realities to eventually declare a winner, albeit not on entirely objective terms.

The largest-scale electroplating activities have always been carried out by the steel industry in an atmosphere largely divorced from traditional metal finishing. Upwards of 20% of all steel produced may be coated, the products of relevance to this chapter being tinplate, its alternative for packaging ‘tin-free steel,’ and zinc electrogalvanized steel in the form of sheet, strip, and wire. During the last twenty years, little advance has been made in the electroplating stage of tinplate production, the electrolytes and additives have changed little, and the plant design remains essentially the same – marked changes have occurred in other aspects of tinplate production, however. The alternative ‘tin-free steel’ or TFS, has settled into a well established sector of the market, largely for lacquered beer and beverage cans and noncritical container applications such as oil, polish, some paints, etc. Its invention is attributed to Japan in the period 1958–1965, and it has been widely exploited. The technology is on the basis of that of tinplate, as a fast cathodic process (1–20 s) in a chromic acid-based solution yielding a coating (<0.1 mm) consisting of chromium metal and chromium oxide,  $\text{Cr}_2\text{O}_3$ .<sup>163,164</sup> Its virtue is cost-effectiveness for every specific application, and as such, it has replaced tinplate for 10–40% of the market, depending upon the country concerned.

By contrast, the zinc coating product area is seeing rapid developments after a relatively static period when hot-dipped and electrogalvanized products occupied well defined niches for thick (20–150  $\mu\text{m}$ ) and thin (5–20  $\mu\text{m}$ ) coatings, respectively. The driving force can be found in the automotive industry which is looking towards car bodies having 5–10-year warranties for which paint and phosphating treatments on steel sheet are inadequate. Two separate types of coated product are emerging. First, electrogalvanizing combined with a modified TFS process giving a highly passivated zinc coating: this is probably the cheapest and easiest option.<sup>165</sup> Second, alloyed zinc electrogalvanizing to give improved sacrificial corrosion performance whilst remaining relatively thin (<15  $\mu\text{m}$ ), a requirement imposed by the body-forming processes. To this end, the zinc alloys favored are those with nickel, iron, manganese, or tin at 0.5–10% levels.<sup>166</sup> It is too early to predict which alloy will dominate the field.

### 4.08.1 Coating Deposition Techniques

#### 4.08.1.1 Nonthermal Spray Deposition Techniques

##### 4.08.1.1.1 Air spraying

Paints, including inorganic paints, may be deposited by a variety of spray guns. Air spraying has also been used to deposit conversion coatings.<sup>1</sup> Air spray guns are simple devices that operate in atmospheric conditions, though they may be housed in a spray booth to

contain fumes and paint spray. Air spray guns are based on venturis. A stream of high-velocity gas is passed through a tube connected to the paint reservoir. The high velocity of the gas lowers the pressure in the venturi and this draws paint from the reservoir and atomizes it. The paint droplets are then propelled toward the substrate by the gas flow. Paint spray guns can be gravity fed or pumped. The high-velocity gas stream is usually compressed air.

High-volume low-pressure (HVLP) spraying is an air spraying variant, which uses a lower-pressure gas supply. The advantage of HVLP is that the deposition efficiency is increased to ~65% compared with something in the region of 30% for standard air spraying. The deposition efficiency can be further improved by using low-volume low-pressure air spraying; however, the coverage rate is decreased.

#### **4.08.1.1.1 Variants of air spraying**

Airless spraying is achieved by using a high-pressure pump to force paint through a spray gun. The advantages of this technique are that uniform thick coats of paint are produced, reducing the number of times an area must be coated. The high pressure also increases the penetration of the paint into surface features such as crevices. Spin spraying is a hybrid process combining spray coating with spin coating.<sup>2</sup> Spray pyrolysis is another hybrid process; a liquid precursor is deposited by air spraying and the coated substrate is then heated to induce pyrolysis.<sup>3</sup>

#### **4.08.1.1.2 Electrostatic spray deposition**

In electrostatic spray deposition (ESD), the deposition efficiency is improved by the use of an applied potential difference between the spray nozzle and the substrate. A liquid feedstock is atomized and charged by being pumped through the nozzle. The electrostatic field between the nozzle and the substrate accelerates the charged droplets toward the substrate.<sup>4</sup> Functional ceramic thin films are one type of coating that has been produced using ESD.<sup>5</sup>

### **4.08.2 Thermal Spraying: An Overview**

The overall technology of thermal spraying is now a century old. A whole list of thermal spraying variants is now currently used in industry, with further developments constantly being made. Dedicated professional and academic societies such as the International Thermal Spray Association, the ASM Thermal Spray

Society, and Japan Thermal Spray Society actively disseminate research results and good practice. There is a high degree of research activity in the area: a brief search of the scientific literature shows that 967 thermal spray papers and patents were published in 2007, as against 624 in 2000, 442 in 1990, and 78 in 1980.

Despite the proliferation of thermal spray variants, the coatings produced in each case share many common features and would all be recognized as thermal spray coatings by Max Ulrich Schoop, the Swiss inventor of thermal spraying, who first established the technology around the beginning of the twentieth century.

In all thermal spray technologies, particles of the coating material are propelled toward the substrate. On impact, the particles deform and adhere to the substrate primarily by mechanical interlocking.

The differences between the various thermal spraying techniques are primarily in the details of how the particles are propelled toward the substrate. Different methods of propulsion result in the particles experiencing different temperatures and velocities while in flight between the spray gun and the substrate. Depending on the process used, particles arrive at the substrate in solid, molten, or partially molten form. Additional variations on the thermal spray theme are created by the form of the feedstock coating material: powder, wire, or molten metal; the use of additional processes to produce hybrid processes such as laser-assisted thermal spraying; the atmosphere in which the spraying is carried out: vacuum or atmospheric.

Thermal spray coatings have a distinctive lamellar microstructure due to the formation of the coating from individual deformed particles, frequently referred to as splats. Porosity is an important issue in thermal spray coatings. Insufficient particle deformation on impact can create intersplat pores. For particles which arrive partially or completely molten, solidification shrinkage can add to porosity. Oxides may also be present in thermally sprayed coatings, which is a particular issue for metallic corrosion-resistant coatings, as in-flight oxidation of particles can result in discontinuous and hence nonprotective oxides in the coating. Another characteristic of as-sprayed thermally sprayed coatings is the distinct substrate-coating interface. In metallic coatings on metallic substrates, this interface is frequently strengthened and simultaneously made more diffusive by a diffusion heat treatment.

Thermal spraying techniques which induce extensive melting, including plasma spraying, flame spraying, and arc spraying suffer from high residual

stresses. These limit the thickness of the coating that will remain adhered to the substrate.

### 4.08.3 Thermal Spraying: Variants

The following table gives an overview of the typical key features of the main thermal spraying variants. Further details of each process are given in the following text ([Table 1](#)).

#### 4.08.3.1 Flame Spraying

Flame spraying is the original thermal spraying process used by the first thermal sprayer, Max Ulrich Schoop. Approximately 100 years later, the technique is still in widespread use. Metals, alloys, ceramic,<sup>8</sup> and polymer coatings may all be formed by flame spraying.<sup>7</sup>

A flame spraying torch is relatively simple, consisting of a flame combined with a system that introduces the feedstock coaxially with the flame. A fuel gas–oxygen mixture is combusted to produce the flame: oxyacetylene is typically used. The feedstock material, which may be in the form of powder, wire, or rod, is continuously fed into the flame and melted. For wire and rod feedstock, the melted material is broken into discrete particles by jets of compressed air. This is not required when a powder feedstock is used. The molten particles are accelerated toward the substrate by the expanding gas flow from the

flame, additional acceleration coming from the compressed air jets if present.<sup>7</sup> Spray distances are typically 120–250 mm.<sup>6</sup>

The type of feedstock used can affect the properties of the final coating. The atomization of molten rod or wire tends to generate finer particles than are found in powder feedstock. The resultant coatings are generally found to be smoother and denser than those formed using powder. The increased smoothness simply results from the finer droplet, and hence splat, size. The effect on density is largely due to the greater degree of melting, which is achieved for rods and wires, as their positioning in the flame can be controlled more precisely than for powder feedstocks.<sup>7</sup>

In addition to atomizing the molten feedstock and providing some acceleration of the sprayed particles, compressed air jets can be used to modify the shape, and hence temperature and flow characteristics of the flame.<sup>7</sup>

The flame may also be controlled by modifying the fuel–oxygen ratio. The highest flame temperatures are achieved when a stoichiometric fuel–oxygen mixture is used. Excess fuel or oxygen will cool the flame simply due to the introduction of a noncombusting material. Fuel-rich mixture is used when spraying metallic coatings, which results in a reducing environment in the flame and hence minimizes in-flight oxidation.

Flame spraying is a low-cost thermal spraying technique. Interfacial bond strengths achievable by flame spraying are generally lower than those of

**Table 1** Characteristics of the different thermal spray techniques

<i>Spraying process</i>	<i>Materials that can be sprayed</i>	<i>Powder size (<math>\mu\text{m}</math>)</i>	<i>Particle velocities (<math>\text{m s}^{-1}</math>)</i>	<i>Deposition rates (<math>\text{m}^2 \text{h}^{-1}</math>)</i>	<i>Interfacial bond strength (MPa)</i>	<i>Coating porosity (%)</i>

other thermal spraying variants.<sup>9</sup> Reproducibility issues are a concern for all thermal spraying methods, but have been reported as being a particular issue for flame-sprayed coatings.<sup>10</sup>

#### 4.08.3.1.1 Variants of flame spraying

High-velocity suspension flame spraying (HVSFS) is a recent development of flame spraying. The key advantage is that very fine powders can be sprayed. Fine powders are normally very difficult to thermally spray, since they do not flow easily. Forming a liquid suspension enables fine powders to be handled in a controlled manner. Once the suspension feedstock is injected into the flame, the liquid is evaporated or burnt off leaving the fine powder in the flame to be heated and accelerated as in any other thermal spray process. The technique is still at a very early stage and the process needs to be optimized; however, demonstration such as the deposition of  $\sim 50\text{-}\mu\text{m}$  thick  $\text{CaO-ZrO}_2\text{-SiO}_2$  indicates that this technique has great potential for corrosion applications.<sup>11</sup>

Reactive flame spraying (RFS) is another process that has been developed from flame spraying. RFS combines flame spraying with self-propagating high temperature synthesis to give a single process in which the feedstock material is both produced and deposited.<sup>12</sup> Clearly, this technique is suitable only for materials that can be formed by self-propagating high temperature synthesis:  $\text{TiC-Fe}$  cermet coatings<sup>12</sup> have been successfully formed by this method. The advantage is that the reaction products are fine scaled; the overall process is low in cost and the energy released by the exothermic reaction acts as an additional heat source.<sup>12</sup>

Flame spraying can be combined with an induction heating postprocessing step to improve corrosion performance by fusing the coating, thereby decreasing porosity and increasing the effectiveness of the coating as a barrier.<sup>13</sup> This has been demonstrated on nickel-based self-fluxing alloys used to protect furnace wall tubes in Taiwanese waste incineration plants.<sup>13</sup>

There are numerous corrosion protection applications for flame-sprayed zinc and aluminum.<sup>9</sup> Flame-sprayed zinc is generally used to protect structural steelwork, and aluminum is used in more demanding applications.<sup>9</sup> Flame-sprayed  $\text{Zn/15Al}$  can provide cathodic protection to steel substrates.<sup>14</sup>  $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-Y}_2\text{O}_3$  glasses have been deposited by flame spraying as candidate corrosion-resistant coatings for engine applications.<sup>15</sup>

#### 4.08.3.2 Wire Arc Spraying

Wire arc spraying is also known as electric arc spraying or arc spraying. In this spraying process, the coating feedstock is a pair of metallic wires, between which an electric arc is struck. The arc melts the ends of the wires; the molten material is then atomized and accelerated toward the substrate by a jet of compressed air.<sup>9</sup> Materials that can be arc sprayed must be electrically conductive, and hence the technique is generally used for metals. Arc spraying is often used to deposit aluminum coatings for anticorrosion applications in the marine and petrochemical industries.<sup>9</sup>

The thermal efficiency of wire arc spraying is greater than that of other thermal spray processes, since the feedstock material is directly heated by the arc.<sup>7</sup> Heating occurs only at the ends of the wires where the arc forms. As soon as the atomized droplets of molten material start to be propelled toward the substrate, they start to cool.<sup>7</sup> Unlike other thermal spray processes, there is no in-flight heating in wire arc spraying, since the droplets are propelled by an air jet as opposed to any kind of flame. Relatively short spray distances of 50–170 mm are used to minimize the in-flight oxidation.<sup>6,7</sup>

Another consequence of the highly localized heating is that the heat input to the substrate is low, primarily because there is no hot gas or plasma jet directed at the substrate.<sup>7</sup> Hence, wire arc spraying can be used to form coatings on materials such as polymers that would not withstand the heat input from other thermal spray processes.<sup>7</sup>

The electric arc must be stable for the spraying process itself to be stable and proceed in a uniform manner.<sup>7</sup> This means that the positioning of the ends of the wires is very important; both the absolute position and feed rate must be accurately controlled in order to maintain a stable arc.<sup>7</sup> The straightness of the wires is therefore significantly more important in wire arc spraying than it is in other wire feedstock thermal spray methods. Wire arc spraying is well suited to high-rate deposition, and hence is used for coating large steel structures including bridges and storage tanks.<sup>7</sup>

##### 4.08.3.2.1 Variants of wire arc spraying

Shrouded arc spraying is a variant of wire arc spraying where an inert gas is used to isolate the sprayed droplets from the surrounding environment, thereby minimizing in-flight oxidation.

### 4.08.3.3 Plasma Spraying

Plasma spraying produces denser and more adherent coatings than does flame spraying.<sup>15</sup> The increased complexity of the spray gun, the power consumption, the requirements of water cooling, and regular electrode replacement as well as the cost of process gases all combine to make plasma spraying costlier than flame spraying.

In plasma spraying, a plasma torch is used to heat and accelerate the feedstock material. The plasma temperature is very high, in the region of 10000K. The flame is capable of melting any material, and consequently, plasma spraying is frequently used to deposit coatings of otherwise difficult-to-melt materials such as zirconia, which are hard to deposit using other thermal spray methods.

The plasma spray gun consists of a central cathode, around which the process gases flow to exit through the anode, which forms the nozzle at the end of the gun. The central cathode is made from thoriated tungsten, as it not only has a high melting point but is also a good thermionic emitter, meaning that it easily releases the electrons required to maintain the arc.<sup>7</sup> The addition of thoria enhances the arc initiation process. The anode is copper, chosen for its high thermal and electrical conductivity, and must be water cooled.

The plasma is generated by a high-voltage discharge between the cathode and the anode. This discharge ionizes the gas between the cathode and the anode, forming a conductive path, which allows an arc to form. The arc heats the gas to temperatures that may exceed 10000K. Due to the very high temperatures created, the gas ionizes to form a plasma. The plasma then expands through the nozzle of the gun, creating a plasma jet, which heats and accelerates any feedstock material injected into it.

A variety of gases may be used to form the plasma. Argon and helium have low enthalpies of ionization; hence it is relatively easy to form a plasma from these gases.<sup>7</sup> An additional benefit of argon is its high atomic mass, which helps to stabilize the arc.<sup>7,16</sup> Nitrogen and hydrogen may also be used, despite their larger enthalpies of ionization, since they improve heat transfer from the plasma to the coating particles.<sup>6</sup> Gas viscosity also needs to be considered: higher gas viscosity reduces the mixing of the plasma with the surrounding air.<sup>10,16</sup> This is advantageous as the hot core of the plasma jet is maintained over a longer distance, improving heat and momentum transfer. In the temperature range of interest, that is, 10000K and above,

argon and helium have high viscosities.<sup>16</sup> Taking these factors into consideration, the gases and gas mixtures used are typically argon, argon–helium, argon–hydrogen, argon–nitrogen, and nitrogen–hydrogen.<sup>6,7</sup> Three gas mixtures of argon–helium–hydrogen and argon–helium–nitrogen have also been used,<sup>7,10,17</sup> an argon–helium–hydrogen mixture being commercially available.<sup>6</sup>

Electrode erosion is an important issue in plasma spraying. A combination of high temperatures and the intense arc means that the electrodes are operating in extreme conditions and consequently need to be periodically replaced. The erosion of the anode is more severe than the erosion of the cathode, resulting in anodes being replaced two to five times more often than cathodes.<sup>7</sup> Electrode lifetimes depend on the operating conditions, but are typically in the range of tens to hundreds of hours.<sup>7</sup> The heat flux in the regions where the arc terminates at each electrode can be in the region of  $10^8 \text{ W m}^{-2}$ .<sup>7</sup> The resulting electrode deterioration can result in the failure of the spray gun and can lead to coating contamination by fragments of the electrodes.<sup>7</sup>

Electrode erosion is most severe when a single arc is struck consistently in the same place. Two approaches have been used to minimize electrode erosion: vortex stabilization and multielectrode guns. Vortex stabilization ensures that the anodic arc root is constantly moving over the anode surface. This is achieved by simply ensuring that the plasma-forming gases have a vortex flow.<sup>7</sup> An alternative is the use of multielectrode guns. Instead of having a single arc, these guns have multiple arcs, each carrying a fraction of the current, and thus decreasing the damaging heat flux at the arc root.<sup>10,18</sup>

#### 4.08.3.3.1 Variants of plasma spraying

The mixing of the plasma jet with surrounding air during air plasma spraying can result in in-flight oxidation of metallic particles.<sup>7</sup> This is generally undesirable, and therefore, several plasma spraying variants have been developed to ensure lower levels of oxidation.

Shrouded plasma spraying (SPS) uses an inert gas to surround the plasma jet in an effort to separate it from the surrounding atmosphere.<sup>7</sup> This can be achieved by simply flooding the area between the nozzle and the substrate with a blanket of inert gas, usually argon or nitrogen.<sup>7,19</sup> The disadvantage of this approach to shrouding is that large volumes of inert gas are used.<sup>7</sup> An alternative that results in a lower usage rate of inert gas is to surround the plasma jet by

a layer of inert gas.<sup>7</sup> These approaches are each achieved by attaching a gas flow device to the front of a plasma spray gun.<sup>7</sup> Both the processes have been shown to produce metallic coatings with significantly lower oxide levels than would be possible with non-SPS. CoNiCrAlY SPS coatings have been reported with 0.3% oxide content,<sup>20</sup> approximately a third to a half of the extent of oxidation expected from atmospheric plasma spraying (APS).<sup>7</sup>

SPS is the cheapest way of plasma spraying in an inert environment, but not the most effective. In order to provide greater separation of the plasma jet from atmospheric air, it is necessary to spray in an enclosed chamber. Such a chamber may be filled with an inert gas as is the case in inert plasma spraying (IPS), or evacuated as it is done in vacuum plasma spraying (VPS) or low-pressure plasma spraying (LPPS).<sup>6</sup> Using such processes essentially eliminates oxidation, oxygen levels of 1500 ppm and 700 ppm being reported for LPPS<sup>21</sup> and VPS<sup>22</sup> respectively.

Another controlled atmosphere variant is high-pressure plasma spraying (HPPS), which is carried out in a pressurized gas-filled chamber, with typical pressures of 100–350 kPa.<sup>23</sup> The higher gas pressures used in HPPS increase heat transfer to the sprayed particles.<sup>23,24</sup> Hence, HPPS is well suited to the spraying of higher melting point materials and is generally used for ceramics. Compared with APS, HPPS coatings have lower porosity levels, improved properties, and uniformity.<sup>23,25</sup> Lower levels of oxidation and contamination are additional advantages.<sup>25</sup>

For IPS, VPS, LPPS, and HPPS, there is a significant increase in equipment cost compared with air plasma spraying due to the requirement of an air-tight or pressure chamber.<sup>10</sup> However, once a plasma spray gun has been installed in an air-tight chamber, it is of course possible to use it in different ways. Controlled atmosphere plasma spraying (CAPS) is an umbrella term covering IPS, VPS, LPPS, and HPPS. CAPS systems are commercially available, which can operate in IPS, VPS, LPPS, and HPPS modes as well as APS.<sup>23,25</sup>

Another plasma spraying variant is radio frequency (RF) induction plasma spraying.<sup>26</sup> An induction coil surrounds the gun, through which the plasma gas and powder feedstock are injected axially.<sup>27</sup> RF torches have a large internal nozzle diameter, which results in relatively low plasma jet velocities, and hence, low particle velocities.<sup>7,27</sup> These are typically 20–50 m s<sup>-1</sup>, that is, an order of magnitude lower than is generally seen for other plasma spray processes.<sup>7,27</sup> This results in particles being in the hot plasma jet for a longer

time, typically ~20 ms compared with ~1 ms for other plasma spray processes,<sup>28</sup> resulting in an increased overall heat transfer.<sup>27</sup> The extensive melting produced by RF plasma spraying results in good spreading of the particles on impact and the production of nearly fully dense coatings.<sup>28</sup> The improved heat transfer also means that larger powder sizes can be used while retaining a high level of particle melting.<sup>27</sup> The key advantage of this is that larger, and hence generally cheaper, feedstock powder can be used.<sup>10,27</sup> Another important advantage of RF induction plasma spraying, particularly for metallic coatings, is the lower levels of oxidation resulting directly from the lower surface-to-volume ratio of larger feedstock powder.<sup>10</sup>

A further development is supersonic RF plasma spraying. In order to generate the higher particle velocities desirable for improved coating properties, supersonic nozzles have been fitted to RF plasma spray guns.<sup>27</sup> In these systems, melting occurs while the particles are at low velocity; they are then accelerated by gas expansion resulting in particle velocities of up to 600 m s<sup>-1</sup> comparable to other plasma spray techniques.<sup>7,27</sup> Another advantage of RF spraying is the absence of electrodes.<sup>28</sup> There is no danger of coating contamination by electrode erosion.<sup>7</sup> It is also possible to use reactive gases in RF, which is ruled out in other plasma spray methods, since contact with the hot electrodes would severely reduce electrode life.<sup>7,28,29</sup>

In plasma-transferred arc (PTA) spraying, an arc is initially generated between a central tungsten cathode and a water-cooled copper anode. The interaction of this arc with the gases flowing through the gun generates a plasma. So far, this is exactly the same as in normal plasma spraying. The difference in PTA is that the ionized gas that forms the plasma provides a conductive path and the arc transfers from the anode and instead strikes the substrate surface.<sup>30</sup> The resulting high heat flux at the substrate surface induces substrate melting. Therefore, on solidification, a metallurgical bond is formed between the coating and the substrate,<sup>30</sup> which is much stronger than the mechanical interlocking that is found in other sprayed coatings. Some dilution of the coating with the substrate is unavoidable, the dilution generally being 5–10%.<sup>31</sup> Since the workpiece becomes part of the electrical circuit, this technique is restricted to electrically conductive coatings and substrates.

#### 4.08.3.4 High Velocity Oxy-Fuel Spraying

The high-velocity oxy-fuel (HVOF) process and the closely related high-velocity air fuel (HVOF) process

both produce relatively dense and oxide-free coatings by accelerating feedstock powder to relatively high velocities in a relatively cool flame. This cool, fast approach ensures sufficient plastic deformation to produce an adherent coating. Due to the lower temperatures used, melting, and hence oxidation, is minimized. HVOF coatings typically have less than 1% porosity. WC-Co coatings are frequently deposited by HVOF; an additional advantage of the lower temperatures is that carbide decomposition is minimized.<sup>10</sup>

In HVOF spraying, powder feedstock is heated and accelerated by expanding combustion gases. Fuel gases are usually hydrogen or hydrocarbon gases like ethylene, propylene, propane, or acetylene,<sup>6,7</sup> though liquid fuels such as kerosene may also be used.<sup>7</sup> As for detonation gun (D-Gun) spraying, the HVOF gun is relatively simple, consisting of a combustion chamber linked to a barrel by a nozzle. Powder injection may be axial or radial.<sup>7</sup> HVOF spray guns require water cooling.<sup>6</sup> Spray distances used in HVOF tend to be a bit higher than those used in plasma spraying due to the enthalpy release in the flame, which may lead to excessive convective heating of the substrate.<sup>6</sup>

A key feature of HVOF spraying is the limited extent of melting. This makes it one of the few thermal spraying processes suitable for spraying nanostructured feedstock, since the feedstock microstructure is retained. The specific corrosion-related interest in forming nanostructured coatings is that the refined grain size may increase the density of fast diffusion paths, hence increasing the speed and effectiveness of passivation.<sup>32</sup> Ji *et al.*<sup>32</sup> have successfully created nanostructured HVOF FeAl-based coatings; however, the corrosion resistance was less than that of the bulk material. Current densities of  $10^{-2}$  A cm<sup>-2</sup> and  $10^{-4.4}$  A cm<sup>-2</sup> were measured in the passive region of potentiodynamic tests in 0.5 M H<sub>2</sub>SO<sub>4</sub> for the sprayed coating and bulk material respectively.<sup>32</sup>

The relatively low temperatures encountered in HVOF and HVOF spraying limit the materials that can be deposited by these methods, since some materials do not exhibit sufficient plasticity at the combustion temperatures, ~3300 and 2300 K, encountered in HVOF and HVOF flames respectively. This means that HVOF and HVOF spraying of high melting point brittle materials such as ceramics becomes difficult.<sup>33</sup> This has led to interest in more highly thermal-efficient guns, such as those with two chambers, which enable easier HVOF spraying of these otherwise problematic materials.<sup>33</sup>

HVOF is a variant of HVOF, which uses a liquid fuel, that is, kerosene. Using a liquid fuel produces

higher gas velocities, and hence higher particle velocities and a lower temperature.<sup>34</sup> This can result in lower oxide content for HVOF coatings compared with those made using HVOF.<sup>34</sup> A disadvantage of using a liquid fuel is the lower deposition efficiency, typically only two-thirds that of a gas-fuelled HVOF gun.<sup>7</sup>

Hasan *et al.*<sup>35</sup> have designed and demonstrated a multipowder feed variant of HVOF, which can create functionally graded materials by simply adjusting the flow rate of powder from each of two separate powder feeders to continuously control the composition of the coating deposited. The idea is that the resultant coating has a gradual change in composition with thickness, which decreases the overall residual stresses.<sup>35</sup>

#### 4.08.3.5 Detonation Gun Spraying

D-Gun spraying is a Union Carbide/Praxair technology that was initially available only as a service with research work appearing only from the mid 1990s onwards,<sup>10</sup> D-Gun WC-Co coatings being a popular research area.

D-Gun spraying can be considered a variant of HVOF spraying, sharing HVOF's advantages of high particle velocity and low temperatures. In D-Gun, spraying powder is injected into the gun along with a mixture of oxygen and fuel. A spark ignites the oxygen-fuel mixture, which explosively combusts. The powder in the combustion chamber is heated and accelerated by the expanding combustion gases, and is directed toward the substrate by the geometry of the gun barrel. This process is repeated at a frequency of 1–55 Hz with a nitrogen purge between each shot.<sup>6</sup>

#### 4.08.3.6 Cold Gas Dynamic Spraying

In thermal spraying, the feedstock is generally heated, commonly to a molten state, to ensure sufficient deformation, and hence bonding on impact. Cold-gas dynamic spraying (CGDS) takes a different approach; here, the emphasis is on increasing particle velocity while maintaining a low particle temperature. Deformation on impact is then solely due to the large momentum of the particles. There is a material-dependent critical velocity, dependent on both particle size and material yield strength, which must be exceeded for deposition to occur. The lack of any significant heating means that CGDS can be used to spray substrates, such as polymers, that would be thermally damaged by other higher heat input thermal spray processes.

Despite the name, there is some heating in CGDS. A carrier gas, typically nitrogen, or helium, or a mixture of one or both of these with air, is compressed and then heated.<sup>6</sup> Helium is more effective than nitrogen at transferring momentum to the injected powder; however, it is also more expensive. Powder is injected into the gas, which then passes through a converging–diverging de Laval nozzle that accelerates the gas to supersonic velocities.<sup>6</sup> The gas is heated, and hence there is some heating of the feedstock powder; however, this is insignificant compared with other thermal spray processes. The temperature of the powder remains well below the melting point<sup>6</sup> and particle temperatures of 500 K have been calculated for CGDS Cu.<sup>6,36</sup>

Although details of particle adhesion in the CGDS process are still under investigation, it can be said that particle melting is avoided and adhesion of particles requires plastic deformation on impact. Therefore, CGDS is suited only to materials that can undergo plastic deformation in the solid state. This rules out ceramics and makes CGDS best suited to ductile metals. CGDS has been successfully used to deposit aluminum,<sup>37</sup> copper,<sup>38</sup> titanium,<sup>39</sup> nickel,<sup>40</sup> nickel alloys<sup>40</sup> as well as some composite coatings such as aluminum with SiC and Al<sub>2</sub>O<sub>3</sub> inclusions,<sup>41</sup> and NiCr with Cr<sub>3</sub>C<sub>2</sub>.<sup>42</sup>

The key advantage of CGDS is the low thermal input, which results in low oxide levels and enables the spraying of substrates that would be thermally damaged by other thermal spray processes.

#### 4.08.3.7 Other Thermal Spray Techniques and Variants

Metallic glasses have good corrosion resistance; however, they are expensive to produce. There is, therefore, interest in producing metallic glass coatings. Iron-based metallic glass has been successfully deposited by gas tunnel plasma spraying.<sup>43</sup> This is a variant of plasma spraying where a vortex flow is used to produce a higher-temperature and higher-energy density plasma than is typical of other plasma spray processes.<sup>44</sup>

#### 4.08.3.8 Liquid Feedstock

Thermal spraying using a liquid feedstock is the current area of interest.<sup>11</sup> Liquid feedstock variants of plasma spraying and HVOF<sup>11,45</sup> have been reported. These including high velocity suspension flame spraying, see [Section 4.08.3.1.1](#). An important advantage of

using a liquid feedstock is that finer particles can be sprayed by spraying a liquid suspension,<sup>11</sup> for example, plasma spraying of submicron WC–Co powder.<sup>46</sup> This results in finer splats, and consequently, a denser microstructure<sup>11</sup>; fully dense Inconel 625 coatings have been reported formed by HVOF spraying of a suspension of fine particles of Inconel 625.<sup>47</sup> For metallic coatings a simple suspension of fine particles is used. There is a second form of liquid feedstock that may be used for ceramic coatings: a liquid containing precursors, referred to as solution precursor plasma spraying.<sup>45</sup>

##### 4.08.3.8.1 Nanostructured coatings

Reports of increased fracture toughness of nanostructured ceramic coatings have led to interest in this area.<sup>48</sup> For processes such as HVOF, where the feedstock powder is not fully melted, it is possible to obtain a nanostructured coating by using a nanostructured feedstock powder.<sup>48</sup> Other thermal spray variants suited for the generation of nanostructured coatings are suspension plasma spraying and solution precursor plasma spraying.<sup>49</sup>

##### 4.08.3.8.2 Laser-hybrid techniques

The various laser-thermal spray hybrid techniques use the additional heat input from a laser beam to enhance the extent of melting to produce a denser coating, thereby improving corrosion resistance, as ingress of corrosive species is inhibited.<sup>50–52</sup> Antou *et al.* showed that an *in situ* laser remelting technique could reduce the interconnectivity of the porosity present in APS YSZ coatings, thus improving the effectiveness of the coating as a barrier to ingress of foreign species.<sup>51</sup> Techniques that melt the entire coating also enhance coating adhesion, as the usual mechanically bonded interface is replaced by metallic bonding.<sup>52,53</sup> An additional advantage is the reduction of residual stresses. The laser treatment and thermal spraying may happen simultaneously<sup>52</sup>; they may alternate or the thermally sprayed coating may simply be laser melted some time after spraying.<sup>53</sup> Provided that suitable laser processing parameters are used to ensure crack-free coatings, laser remelting can significantly improve corrosion resistance.<sup>52</sup> One of the many examples is the use of a hybrid laser-flame spraying method to generate Metco 12C coatings with a superior corrosion resistance to similar HVOF coatings.<sup>52</sup>

An extreme of the hybrid spray techniques is surface alloying of a preplaced thermally sprayed coating, a method, which can be used to enhance corrosion

resistance.<sup>54</sup> Electron beam melting of a flame-sprayed Al coating has been used to enhance the corrosion resistance of the underlying Mg alloy substrate.<sup>54</sup>

#### **4.08.3.9 Thermal Spraying: Periphery Processes**

##### **4.08.3.9.1 Preprocessing processes**

Abrasive blasting is widely used to achieve suitable surface roughness and to activate the surface by removing any preexisting oxides.<sup>55</sup> Substrate preheating is less widely used and its effectiveness varies with the deposition method. It has been shown to enhance substrate wettability for flame spraying. A similar, though lesser, effect was seen for plasma spraying of Al on mild steel. In HVOF spraying, minimal melting occurs, and hence there is no wettability-linked effect of preheating; however, some increase in adhesion was noted, highlighting the different bonding mechanism in HVOF coating.<sup>55</sup>

##### **4.08.3.9.2 Postprocessing techniques**

Various posttreatments are frequently used with thermally sprayed coatings. These enable higher quality coatings to be produced than can be formed from simply optimizing spraying parameters.<sup>50</sup> The prime reason for this is a desire to eliminate the detrimental effect of porosity, particularly interconnected porosity. Organic sealants can be applied to seal the sprayed coating<sup>56,57</sup>; however, such sealants may have a relatively low maximum operating temperature.<sup>58</sup> Alternatively, corrosion resistance can be ensured by adding a corrosion-resistant layer between the substrate and coating. This technique is used when the outer coating has an additional function. Aluminum bond coats have been successfully used in this role in HVOF wear-resistant WC–Co coatings on Mg alloy substrates that otherwise corrode rapidly in salt spray tests.<sup>56</sup> MCrAlY bond coats are widely used in the same role in thermal barrier coatings. A further variant has been demonstrated by Ishikawa *et al.*,<sup>58</sup> who used a duplex wire flame-sprayed system consisting of an 80Ni–20Cr underlayer covered with a layer of aluminum. The outer aluminum layer then improved corrosion resistance by acting both as a sacrificial anode and essentially as a sealant.<sup>58</sup>

Laser remelting has successfully improved the salt spray resistance of plasma-sprayed Ni-coated WC coatings by densification on resolidification, reducing the porosity from an initial 6.67% to 0.76%.<sup>59</sup> The alternative process of vacuum annealing was also used on the same coatings, which also decreased the

porosity but was less effective, resulting in 2.24% porosity.<sup>59</sup> Induction heating is another remelting process that has successfully been used to seal porosity, and hence improve the effectiveness of thermally sprayed coatings as barriers to corrosive species.<sup>13</sup>

#### **4.08.4 Corrosion Applications of Metallic Sprayed Coatings**

Large scale steel structures such as bridges, girders, and ski lifts are commonly provided with corrosion protection by thermally sprayed coatings.<sup>6,7</sup> For such applications, zinc and aluminum, as well as their alloys, are widely used.<sup>7</sup> Coating thicknesses of 50–500  $\mu\text{m}$  are typical.<sup>7</sup> Thermally sprayed aluminum coatings are also used to protect a large number of steel marine structures, including components on off-shore oil rigs.<sup>7</sup> These coatings are generally deposited by arc spraying<sup>6</sup> or flame spraying.<sup>7</sup> Zinc is also used for some immersion applications such as components on dams.<sup>7</sup> Other uses of thermally sprayed aluminum include preventing corrosive chemicals from attacking storage containers.<sup>7</sup> For most of these applications, any porosity present, as is typical of thermal spray coatings, will not be a great problem, because both zinc and aluminum provide cathodic protection. Hence, the corrosion protection provided by these coatings is not lost by simple breaches in the coating.<sup>7</sup> However, if the coatings are to be used in immersed conditions or if there is any danger of aluminum–thermite sparking, a sealant is used.<sup>7</sup>

In the automotive industry, wire arc- or flame-sprayed aluminum coatings are used to protect various exhaust components from hot corrosion.<sup>7</sup> Wire arc-sprayed zinc has been used to provide corrosion protection for steel steering stop brackets.<sup>7</sup> There is a clear driving force for the increased use of light alloys, specifically aluminum and magnesium alloys in the automotive industry. In many potential automotive applications, coatings are required to improve both the wear and corrosion resistance of the underlying alloy. Magnesium alloys particularly need to be protected against corrosive environments. There is great scope for the use of thermally sprayed coatings, particularly APS and HVOF, in such applications.<sup>60</sup>

The relatively low melting point of aluminum, 660°C, restricts the use of these coatings to maximum service temperatures of  $\sim 550^\circ\text{C}$ .<sup>7</sup> MCrAlY coatings tend to be used for high temperature corrosion protection; such coatings would generally be deposited by plasma spraying or HVOF.<sup>61</sup>

The harsh operating environments encountered in gas turbines are withstood only with the aid of various coatings. MCrAlY alloys are widely used to provide high temperature corrosion resistance. These alloys are used both as overlay coatings on components such as stators and as the bond coat in thermal barrier coatings.<sup>7</sup> VPS and LPPS are the techniques most commonly used to deposit these coatings.<sup>6</sup> This minimizes the formation of noncontinuous, nonprotective oxides during coating deposition, which would decrease the corrosion protection offered by the coating.

Boilers require high temperature corrosion resistance in aggressive environments; these are frequently thermal sprayed to protect against temperature, abrasion, and corrosive elements from fuel.<sup>6,7</sup> Plasma spraying, wire arc spraying, and HVOF coatings of stainless steel,<sup>6</sup> nickel alloys, high-chromium alloys, and chromium–nickel alloys<sup>7</sup> have been used to extend the life of boiler components such as superheater tubes and waterwalls.

Very demanding corrosive conditions are encountered in the glass-making industry.<sup>7</sup> The only materials that can withstand extended contact with molten glass are the precious metals and their alloys.<sup>7</sup> Precious metal glass-making components are often coated with thermally sprayed ceramics in order to extend corrosion life.<sup>7</sup> Plasma-sprayed molybdenum or molybdenum alloys are used to protect a variety of glass-making components, including moulds and stirrers.<sup>7</sup>

Unsurprisingly, corrosion-resistant coatings are required in the chemical processing industry where aggressive chemicals are stored and piped.<sup>7</sup> APS nickel-based alloys, including Hastelloy C, Hastelloy B, and Inconel 600, have been successfully used to extend the service life of pressure vessels.<sup>7</sup> Plasma-sprayed niobium doped with palladium has been used to protect welds in aluminum alloy tanks used to contain nitric acid.<sup>7</sup> Various glass-lined chemical reactors have been repaired using APS tantalum.<sup>7</sup> HVOF spraying of a molybdenum coating on stainless steel components used in a high temperature sulfur and ammonia environment has proved to be a cost-effective alternative to component replacement.<sup>6,62</sup>

Applications of thermally sprayed corrosion resistance coating in the petrochemical industry include HVOF-sprayed tungsten carbide coatings used to increase wear as well as corrosion resistance of valves.<sup>7</sup> Such coatings are also used to protect the blades of cutting machines in the paper industry.<sup>7</sup> HVOF stainless steel coatings with high molybdenum contents are

used to provide corrosion resistance to dryer rolls used in tissue making.<sup>7</sup> APS NiCrSiB/CuSn/MoS<sub>2</sub> coatings have successfully increased the lifetime of steel hydraulic mine props by providing protection against corrosive attack by mine water.<sup>6,63</sup>

The formation of sacrificial anodes for cathodic protection systems is another corrosion-related application of thermal spraying.<sup>7</sup> Plasma spraying and arc spraying have been used to deposit zinc and titanium sacrificial anodes; flame spraying has also been used for zinc.<sup>7</sup> Whether or not a given coating will act as a sacrificial anode depends on the substrate material and the surrounding electrolyte as well as any impressed current.<sup>7</sup> Semiconducting ceramics can be used as sacrificial anodes in impressed current systems. These can also be made by thermal spraying.<sup>7</sup> Plasma-sprayed ferrite coatings have cathodically protected metals such as titanium, niobium, and tantalum when they have been used in oil or specific chemical environments.<sup>7</sup>

The general increasing acidity of printing inks as well as the tight tolerances required result in several applications of thermally sprayed coatings in the printing industry.<sup>7</sup> Engraver rolls are coated with APS ceramic, either TiO<sub>2</sub>–Al<sub>2</sub>O<sub>3</sub> or Cr<sub>2</sub>O<sub>3</sub>, which, as for TBCs, is deposited on top of a metallic bond.<sup>7</sup> The bond coats used for engraver rolls are made using APS.<sup>7</sup> In this application, it is interesting to note that the large size of the components is instrumental in the choice of thermal spray method, the rolls being far too large for any CAPS chamber.<sup>7</sup>

APS may also be used for the large rolls used in continuous annealing lines.<sup>6</sup> These rolls require coatings that provide both wear and corrosion resistance<sup>6</sup>: cermets such as Cr<sub>2</sub>C<sub>3</sub>/NiCr and MCrAlY/oxide deposited by APS, D-Gun, or HVOF spraying.<sup>6,64</sup>

The provision of alternative coatings to hard chrome is an important area in which thermal spraying can be applied.<sup>7,65</sup> HVOF WC–Co is widely used as a hard chrome replacement. Both the US air force and navy use HVOF WC–Co, which resulted from the work of the Hard Chrome Alternatives Team (HCAT) set up by the United States military, on landing gear components.<sup>7</sup> However, the dimensions of HVOF guns rule out HVOF spraying of some components, particularly inner diameters of landing gear and hydraulic components.<sup>66</sup> For such applications, plasma spraying may be used. The Sulzer Metco F300 gun has been demonstrated to be able to coat components with inner diameters of 1.6 in.<sup>66</sup> A standard spray gun is fitted with an extension to permit insertion into internal diameters. These tend to

be 12 or 24 in. long, and it is the length of the extension that limits the depth to which spraying can occur.<sup>66</sup> Both Praxair and Sulzer Metco produce guns specifically for inner-diameter spraying applications.<sup>66</sup> The rotation of the component around the gun ensures uniform coating deposition.<sup>66</sup>

In other applications, such as the coating of engine cylinders, a rotating gun is used. These are commercially available and include the SulzerMetco RotaPlasma<sup>®</sup>. From approximately 2000 onwards, Volkswagen has routinely used a 200- $\mu\text{m}$  thick air plasma-sprayed Fe–Mo coating on the cylinder walls of diesel and petrol engines. These coatings enhance both the tribological performance of the underlying aluminum alloy and corrosion resistance.<sup>67</sup>

#### 4.08.5 Corrosion Applications of Inorganic Sprayed Coatings

Thermal barrier coatings (TBCs) are perhaps the most widely known example of thermally sprayed inorganic corrosion-resistant coatings. TBCs consist of two layers. The inner layer is a metallic bond coat, which is frequently a VPS- or LPPS-deposited MCrAlY ( $M = \text{Co}, \text{Ni}, \text{or NiCo}$ ) coating.<sup>61</sup> A relatively recent innovation is the use of HVOF to deposit denser bond coats.<sup>61</sup> An important role of the bond coat is to enhance adhesion of the outer layer. For nonrotating components, APS zirconia is frequently used for the outer layer, with electron beam physical vapor deposition used to deposit the ceramic outer layer on rotating components. The main role of this outer ceramic layer, the top coat, is to form a thermal barrier, protecting the underlying component from the high temperatures of the hot gas path, and thus improving corrosion resistance. A  $\sim 250\text{ }\mu\text{m}$  top coat can reduce the surface temperature of the underlying component by 200K.<sup>68</sup> The thermally grown oxide that forms on the underlying MCrAlY bond coat in service is the main corrosion protection mechanism in TBCs.<sup>68</sup> TBCs are used on various components along the hot gas path, including combustors and nozzle guide vanes.

Among other corrosion uses of thermally sprayed ceramic coatings, APS  $\text{Al}_2\text{O}_3\text{--TiO}_2$  coatings have been used to protect blast furnace stove cooling pipes from carburization.<sup>6,69</sup>

Conversion coatings are widely used to enhance corrosion resistance. The chemical treatment of the material to be protected produces a surface layer of insoluble compounds, usually oxides, chromates, or phosphates.<sup>70</sup> This layer acts as a barrier between the

substrate and the corrosive environment.<sup>70</sup> Air spray is one method that has been used for the deposition of cerium oxide conversion coatings, which are chromate-free alternatives to chromate conversion coatings.<sup>1,71</sup>

There is a wide variety of commercially available zinc-pigmented paints and zinc-rich coatings. These typically consist of zinc in an organic binder; however, inorganic versions are available. The inorganic zinc-based coatings use a silicate binder in place of the epoxy binders used in the more established organic zinc-based coatings. Zinc silicate coatings can outperform zinc epoxy coatings.<sup>72</sup> As with the organic versions of such coatings, the inorganic zinc coatings can also be used in multilayer coating systems.<sup>72</sup>

### Glossary

**Laser-assisted thermal spray** Laser-assisted thermal spraying is a one-step coating method, in which a high-power laser is combined with thermal spraying to create denser and more adherent coatings, with a metallurgical bond between the coating and the base material, than achieved by normal thermal spraying processes.

**Laser chemical vapor deposition (LCVD)** Laser chemical vapor deposition is a technique to deposit thin to moderate films by a chemical reaction activated by a laser beam inside a gas chamber via either a pyrolytic or a photolytic effect.

**Laser cladding (LC)** Laser cladding is a process for fusing a powdered/wire/sheet material by using a laser on a substrate with minimum dilution.

**Laser melt/particle injection (LMI)** Laser melt/particle injection is a process for generating a metal matrix composite on a substrate by the injection of ceramic/higher melting point particles into a laser-induced melt pool.

**Laser surface alloying (LSA)** Laser surface alloying is a process that utilizes a laser to melt a metal coating and a portion of the underlying substrate to form a surface layer that is different from the coating and the substrate.

**Laser surface melting (LSM)** Laser surface melting is a process in which a thin layer of substrate surface is melted by a high-power laser beam and followed by rapid solidification to alter surface microstructures.

**Pulsed laser deposition (PLD)** Pulsed laser deposition is a thin-film deposition technique in which the target material is ablated by a high-power pulsed laser beam inside a vacuum or an inert-gas chamber and then deposited as a thin film on a substrate.

LASER is an acronym for light amplification by stimulated emission of radiation. Material processing with lasers takes advantage of virtually all the characteristics of the laser beam, including monochromaticity, coherency, high radiance, low beam divergence, and the ability to focus on a small spot.

When a laser beam strikes an opaque surface, a part of the radiation is reflected and the remaining part is absorbed in the substrate of the material. The absorption process depends on beam wavelength, temperature, and nature of the surface. Shorter wavelengths, elevated temperatures, and rougher surfaces usually lead to a higher absorptivity for metallic materials. The absorption of laser energy results in the excitation of free electrons (in metals), vibrations (in insulators), or both (in semiconductors). This excitation energy is rapidly converted into heat, and followed by various heat transfer processes such as conduction into the material and radiation from the surface. The generation of heat at the surface and its conduction into the material establish the temperature distribution in the material. Depending on the thermophysical properties of the material and laser parameters, a thin layer of the material surface could be heated, melted, or even vaporized, and then followed by rapid solidification to generate refinement/homogenization of microstructures.

Many types of lasers have been operated in material processing, but only four types of lasers are of sufficient energy and robustness to be used effectively for surface treatments: the  $\text{CO}_2$  laser (with wavelength of  $10.6 \mu\text{m}$ ), the Nd:YAG laser ( $1.06 \mu\text{m}$ ), the high-power diode laser (HPDL:  $800\text{--}950 \text{ nm}$ ), and the excimer laser ( $248 \text{ nm}$  for KrF). Due to their long wavelengths, surface modification by continuous-wave (CW) multikilowatt  $\text{CO}_2$ , Nd:YAG, and HPDLs occurs through heating effects, with a typical melt depth in the range of  $50 \mu\text{m}\text{--}2 \text{ mm}$ . In contrast, the excimer laser is pulsed and ranges in energy up to  $1 \text{ J}$  per pulse. Due to the short wavelength, surface modification by an excimer laser occurs through a combination of photochemical and heating effects. The typical melt depth caused by

an excimer laser is a few micrometers, with a much faster cooling rate compared with the other three lasers. Recently, many special features of HPDL interaction with materials have been identified.<sup>1</sup> These features include better surface finish, better beam absorption, better morphological characteristics, more consistent and repeatable results, fewer cracks, and less porosity generation. These benefits are due to the multiple beam integration and shorter wavelength of the HPDLs, compared with Nd:YAG and  $\text{CO}_2$  lasers. In addition, HPDLs have the advantages of being potentially low in cost, high in energy efficiency, and more reliable, as well as having longer service life, and portability. Therefore, HPDLs are ideal for industrial applications of surface treatments.

**4.09.2 Solidification Microstructures**

Solidification induced by a laser beam leads to high solidification rates due to the rapidly moving temperature fields and the associated high cooling rates and large supercooling. At very high solidification rates (greater than the local diffusion rate), equilibrium at the interface cannot be established and the solute atoms are frozen into solid at the same composition as they arrive at the interface (solute trapping).<sup>2</sup> This provides a unique opportunity for the development of a wide variety of novel alloys with extended solid solution. These alloys with nonequilibrium phases offer the possibility of new materials with properties that cannot be achieved by conventional processing techniques. In addition, the rapid cooling rate results in the homogenization/refinement of microstructure and dissolution/redistribution of precipitates or inclusions. In the case of CW lasers with a multikilowatt power level, a cooling rate of  $10^3\text{--}10^6 \text{ K s}^{-1}$  is quite common. The cooling rate can rise up to  $10^{11} \text{ K s}^{-1}$  for the low energy input surface skin processes.<sup>3</sup> The solidification microstructure is determined by the constitutional supercooling theory. For a specific alloy, the solidification microstructure depends on the local solidification conditions, that is, solidification rate,  $R$ , and temperature gradient,  $G$ , at the solid-liquid interface. In general, the morphology of solidification microstructures can be described as planar, cellular, cellular/dendritic, or dendritic, depending on  $GR$ . The values of  $G$ ,  $R$ , and  $G/R$  vary within the melt pool. Therefore, different solidification morphologies can be found, for example, with a planar front zone at the melt pool-substrate interface and then cellular and dendritic

structure toward the surface of the melt pool. On the other hand, the size of microstructure, which is often characterized by the secondary dendritic arm spacing, is determined by  $G/R$ , which is the cooling rate. The higher the cooling rate, the finer the resulting microstructure.

### 4.09.3 Laser Applied Coatings

A wide range of laser applied coating techniques is available today. Laser cladding (LC) and laser melt/particle injection are usually used to provide thick coatings with minimum dilution of substrate material. Laser surface remelting is applied to coatings produced by conventional techniques, such as thermal spraying, in order to modify microstructures and eliminate defects for the improvement in properties. Laser-assisted thermal spraying, also called laser hybrid spraying, is a one-step coating method, in which a high-power laser is combined with thermal spraying, to create denser and adherent coatings with much increased processing efficiency than normal thermal spray process. Pulsed laser deposition (PLD) and laser-assisted chemical vapor deposition (LCVD) produce thin films. Laser surface alloying (LSA), on the other hand, is applied to alter surface chemistry and composition by melting and mixing the substrate, with a coating material or a component of a gas, and can be used for either thick coatings or thin films.

#### 4.09.3.1 Laser Cladding

LC is used to produce a relatively thick, typically from 50  $\mu\text{m}$  to 2 mm, and homogeneous overlay of coating material on the substrate with a fusion bond. LC can be achieved by a high-power laser beam to slightly melt the surface of the substrate with simultaneous delivery of powdered materials into the molten pool, as described in [Figure 1](#). LC can be also performed by completely melting materials predeposited on the substrate or through wire feeding with minimum dilution.

LC has many advantages over conventional cladding techniques such as thermal spray and arc welding. These advantages include a fusion bond and a reduction (or elimination) of porosity and cracks in comparison with thermal spray; a reduction in dilution (typically <5%), extremely narrow heat-affected zones with a low thermal distortion, and a reduction in postcladding machining costs in comparison with

arc welding. For most LC applications in the field of surface protection, CW  $\text{CO}_2$  and Nd:YAG lasers are typically used. However, in recent years, HPDLs have been increasingly used, especially in industrial environments, with the advantages of a reduction of operating and investment cost, high plug efficiency, and compact size. LC enables the generation of very fine, homogenous microstructures and nonequilibrium alloys due to the inherent rapid cooling rate associated with the process, which promotes the formation of either an amorphous phase or nonequilibrium crystalline phases with extended solid solution.

LC has found relatively widespread use for the protection of materials against corrosion and oxidation in a variety of applications, including Al alloys, Mg alloys, carbon steels, stainless steels, and various metal matrix composites. LC on Mg alloys with Al, Al alloys, and other alloying elements significantly enhances the corrosion resistance, along with wear resistance. For example, the corrosion rate of laser-clad  $\text{Mg}_{27}\text{Al}_{73}$  is one order of magnitude lower than that of commercially produced AZ91B and two orders of magnitude lower than that of Mg in 3.5% NaCl solution.<sup>2</sup> This is due to the passive film on the clad material, which is much more stable than that of the AZ91B and Mg substrates, due to the refinement of microstructure and extended solid solution of Al. Additionally, LC of amorphous alloy  $\text{Zr}_{65}\text{Al}_{7.5}\text{Ni}_{10}\text{Cu}_{17.5}$ , with a thickness of 1.5 mm, on a commercially pure Mg substrate resulted in corrosion resistance and wear resistance superior to those of the uncoated substrate, with the corrosion current density being lowered by three orders of magnitude in 3.5% NaCl solution.<sup>5</sup> In addition, the corrosion current density of laser-clad  $\text{Al}_2\text{O}_3$  is three orders of magnitude lower than that of AZ91HP Mg alloy in 3.5% NaCl solution.<sup>6</sup>

LC can also be applied for extending the solid solubility limits of rare-earth additions (e.g., yttrium, rhenium hafnium, and cerium) in nickel-based superalloys to improve their resistance to oxidation at elevated temperatures. Under equilibrium conditions, the maximum solid solubility of rare-earth metals is  $\sim 0.2 \text{ wt}\%$  at room temperature. However, alloys produced by LC of Ni-(Fe,Cr)-Al-Hf-Re resulted in a uniform distribution of alloying elements in the clad matrix with an extended solid solubility of alloying additions, a greatly refined microstructure, and the formation of metastable rhenium- and hafnium-rich phases.<sup>7,8</sup> Under thermal cycling oxidation conditions, the clad material exhibits negligible change in weight, while the substrate

**Figure 1** Laser cladding with coaxial powder feeding.<sup>4</sup>

(Rene80) suffers from extensive spalling of the scale.<sup>9</sup> In addition, LC of NiCrAlY alloy on a Hastelloy X substrate produces a columnar dendritic structure, free of porosity and microcracks, consisting of  $\gamma$ -Ni solid solution and a small amount of  $\text{Al}_5\text{Y}_3\text{O}_{12}$  close to the surface, which exhibits excellent isothermal oxidation behavior.<sup>10</sup>

A new type of thermal barrier coating (TBC) has been developed for gas turbine blades by LC of yttria-stabilized zirconia (YSZ) on superalloy substrates.<sup>11</sup> The LC produces an oriented epitaxial growth, closely packed columnar structure during rapid solidification processing. This promotes the formation of an alumina layer between the NiCoCrAlY layer and the columnar ceramic layer that provides the adherence of the columnar layer to the NiCoCrAlY layer. A good metallurgical bond between the  $\text{ZrO}_2$  layer and the NiCoCrAlY alloying layer, and between the alloying layer and the substrate. The chemical modification of  $\text{ZrO}_2$  can be adopted to eliminate microcrackings of the coatings. The oxidation resistance of such laser-clad thermal barrier coatings in air at  $1200^\circ\text{C}$  is significantly higher than that of plasma-sprayed coatings. In addition, LC with 60% Ni, 19% Cr, 11% Al, and 6.4% Fe showed an excellent corrosion resistance than the Incoloy 800H,<sup>12</sup> so that these coatings can be used as an oxidation barrier in high temperature applications at temperature levels over the maximum limit where the Incoloy 800H can be used.

Titanium-based alloys are high-strength, light materials used extensively in the aerospace industries for airframe structures and component parts of aircraft engines (e.g., airfoils). However, titanium alloys have poor oxidation resistance at temperatures above

$600^\circ\text{C}$ . The most critical section of the airfoil is its tip, which is generally exposed to high temperatures  $>500^\circ\text{C}$  during engine operating conditions. LC of 50Nb–50Ti alloy on the tip of airfoils (Ti–6Al–4V alloy) has resulted in an excellent oxidation resistance at  $1000^\circ\text{C}$  in air. In contrast, the unclad Ti–6Al–4V alloy formed a 500- $\mu\text{m}$  thick, porous oxide layer, which tends to spall from the substrate, forming a 100- $\mu\text{m}$  oxide in 48 h with a good adherence.<sup>13</sup> Important features of such LC processes for industrial applications include that the laser beam is capable of following the contour of the airfoils; good bonding between the laser-clad niobium and airfoils, and readily controlled thickness and composition of the clad.

In municipal waste incinerators (MWI), critical components such as superheater or boiler tubes are often degraded by corrosion. Especially in modern waste-to-energy (WTE) plants, the need for increased efficiency requires operation at higher temperatures, which in turn enhances the corrosion rates. LC has been successfully used for the production of anticorrosion and antierosion coatings on superheater and boiler tubes. Compared with protective coatings produced by flame spraying, LC is virtually porosity free and ensures metallurgical bonding to the substrate, so that the clad tubes can be bent without any damage from cracking or spalling. This is an important development for the construction of the bends of the superheater coils and the production of integral laser clad superheater assemblies. One automatic diode laser workstation available for industrial production of MWI superheater and boiler clad tubes has been demonstrated and installed in European MWI plants.<sup>14</sup>

#### 4.09.3.2 Laser Surface Melting

In the laser surface melting (LSM) process, a thin surface layer is rapidly melted by a high-power laser beam, followed by a rapid solidification to produce a microstructure different from that of the bulk material. High cooling rates of the molten surface layer can promote the formation of an amorphous material, metastable phases, or a fine-grained microstructure resulting in improved surface properties, such as wear, corrosion, and fatigue resistance. The principal advantage of LSM is that it alters the microstructure without changing the composition, compared with other laser surface modification techniques introduced later. More importantly, LSM has been utilized as a posttreatment for other surface coating techniques. The most commonly encountered example is laser melting of thermally sprayed coatings. In this case, it is also referred to as laser remelting.

Thermal spraying processes are widely used to apply a variety of coatings, including metallic coatings, metal matrix composite coatings (MMC), and ceramic coatings, on different substrates. However, despite the efforts made to improve spraying techniques, such as high-velocity oxy-fuel (HVOF) and plasma spraying, the coatings may still exhibit certain defects such as unmelted particles, oxide layers at splat boundaries, porosity, and microcracks, which are detrimental to corrosion performance. Furthermore, the bonding to the substrate is usually not metallurgical or fusion based. Interconnected porosity and lamellar grain, splat-structures, with oxide inclusions at interlayer boundaries, result in potential failure of the coatings due to penetration of corrosive agents into the interlayer and eventual debonding of the coatings. The use of LSM to modify the structures of thermal sprayed coatings is referred to as laser sealing or laser glazing. In this technique, melting is induced in the near-surface coating by a relatively high intensity and short duration of laser irradiation.

For thermally-sprayed metallic coatings, laser melting is an effective technique for a significant improvement in the corrosion resistance by elimination of defects in the original thermal-sprayed layers. Normally, high-power CW lasers, such as CO<sub>2</sub> laser, Nd:YAG laser, and HPDLs, are chosen with appropriate selection of laser operating conditions enabling fully controllable melt pool dimensions. Therefore, thermal-sprayed coatings can be either partially melted (i.e., top-layer only), or fully melted (i.e., whole layer together with a small portion of substrate material). In both the cases, the defects in the original

thermal-sprayed coatings can be completely eliminated, while fully melting offers an advantage of the formation of a metallurgical bond compared with the mechanical interlocking in the original coatings. For example, plasma-sprayed Ni31Cr11Al0.6Y coating on Alloy 800H, as a physical barrier to carbon ingress, improves the metal dusting resistance, with limitation due to the presence of interconnected porosity. Laser remelting of such coatings further improves the metal dusting resistance of the thermal-sprayed coated alloys due to improving the effectiveness of the coating by elimination of interconnected porosity.<sup>15</sup> In addition, laser remelting of HVOF-sprayed Inconel 625 coatings resulted in the homogenization of the sprayed structure, and the removal of oxide inclusions between splats and interconnected porosity, leading to a significant improvement in resistance to wet corrosion and high temperature corrosion. The corrosion resistance of the sprayed coatings after laser treatment is equivalent to that of the wrought alloy.<sup>16</sup>

For MMC, which are normally applied using HVOF, apart from the role of common defects of thermal-sprayed coatings described earlier, the corrosion processes are dominated by complex microgalvanic and interfacial mechanisms. First, the interface between the hard phase and the matrix represents a physical microcrevice, providing an inherent driving force for localized attack due to classic mechanisms of differential aeration; second, the difference in electrochemical potentials between the coating constituents provides additional driving force for localized corrosion due to microgalvanic corrosion. Third, the existence of interconnected porosity and lamellar grains, splat-structures with oxide inclusions at interlayer boundaries results in another major concern to the failure of the coatings due to corrosion penetration into the interface and eventually debonding of the coatings. Laser remelting of such HVOF MMC coatings is an obvious option owing to its unique features over conventional heat-treatments, for example, precise control of treatment depth with or without melting. The resultant microstructural homogenization, such as the removal of the splat-structure and porosity, the reduction of sharp compositional gradient between the hard phase and the matrix, and the improvement in adhesion bonding between coating and substrate, can be readily achieved. Compared with metallic coatings, special attention should be paid to an appropriate selection of laser operating conditions to avoid formation of

cracks and porosity within laser-melted layers. Laser remelting of Inconel 625-based tungsten carbide (WC) HVOF-sprayed MMC coatings significantly improves the corrosion resistance as a result of the elimination of a discrete splat-structure, microcracks, and porosity, and also reduces the microgalvanic driving force between the WC and the metal matrix. In addition, an improved wear resistance of the laser-treated coatings results due to the formation of a faceted dendritic structure of the WC phase.<sup>17</sup> Therefore, laser remelting shows potential benefits for the improvement in HVOF coatings in tribocorrosive environments.

A typical example of ceramic coatings is thermal barrier coatings consisting of  $\text{ZrO}_2 + 8 \text{ wt\% Y}_2\text{O}_3$  as the outer coating and NiCrAlY layer as a bond-coat on Ni-base substrate. Such TBC coatings, normally applied by plasma spray on hot-section components of gas turbines, offer significant advantages of increased operating temperatures and protecting the coatings from hot corrosion. The coatings retain a substantial amount of interconnected pores and microcracks, with high porosity providing a better thermal protection. However, the life of the coatings is limited by the oxidation of the metallic bond coat due to the penetration of corrosive fuel through the porosity, which causes the failure of the coatings by the spalling of ceramic coating layer. Laser surface remelting shows great potential for the improvement in plasma-sprayed thermal barrier coating properties by reducing surface roughness, eliminating open porosity on the surface, and modifying microstructures from lamellar to columnar. In laser-melted ceramic materials, cracks frequently occur in the densified layer perpendicular to the surface, generated by shrinkage and thermally induced stresses. However, it is possible to generate a controlled segmented crack network by properly selecting laser operating conditions, so that improvement in thermal shock resistance can be achieved. For example, laser glazing increases thermal cyclic lifetimes of plasma-sprayed thermal barrier coatings about fourfold by improving the strain accommodation through segmented cracks.<sup>18</sup> Laser glazing has also resulted in enhancement, approximately fourfold, in the lifetimes of plasma-sprayed thermal barrier coatings by in high temperature corrosion tests involving  $\text{V}_2\text{O}_5$  salts.<sup>19</sup> However, the existence of macroscopic vertical cracks may provide a path for oxygen and molten salts to attack the TBC system. Therefore, special care must be taken in the consideration of a compromise between the desirable and undesirable properties.

#### 4.09.3.3 Laser-Assisted Thermal Spray

As described earlier, the improvement in integrity and performance of thermal-sprayed coatings can be achieved by laser remelting. However, such a process requires additional steps. Although LC has a potential to be developed as an effective technique for coatings in practice, it is inefficient for large-area coverage in industrial applications; more than 10 times slower than thermal spraying in terms of materials deposition rate. In addition, LC of ceramic materials also produces numerous macrocracks.

An effective combination of laser processing and conventional thermal spray systems, namely laser-assisted thermal spray, has been developed and provided the opportunity for depositing dense coatings on large surface areas with improved structural integrity and performance, and acceptable process efficiencies for industrial applications. The laser in such a combined system can be used to reduce microstructural defects, improve cohesion within the coatings, and achieve fusion bonding between the coating and the substrate. The thermal spray jet can provide an effective heat source for increasing the processing rate (relative to LC) and controlling the temperature gradients and thermal stresses during processing. This could be of considerable benefit to process and manufacturing engineers.

Lasers can be combined with various types of thermal spray techniques. For example, laser-assisted flame hybrid spraying process has been developed to deposit alumina coatings on alumina-based refractory ceramics.<sup>20</sup> Flame spraying is a cost-effective and highly flexible surface coating technique; however, the resulting coatings are porous and have a low mechanical bonding to the substrates. LSM can produce very dense surfaces and fused bonded layers; however, cracks in the treated layers readily occur and the process velocity is often too slow for industrial applications. The combination of flame spraying and laser beam decreases, and may even overcome the drawbacks of the individual processes, thus forming an efficient method for depositing coatings with improved structural integrity. Coatings with dense microstructures and fusion-bonded to the substrate are especially desirable for refractory materials used for lining furnaces and incinerators. In addition, laser-assisted plasma spray systems have been used to produce dense NiCrBSi coatings on small mild steel components,<sup>21</sup> and to deposit a Ni/Ti coating onto a Ti-6Al-4V substrate.<sup>22</sup> The shear strength of the Ni/Ti coating was increased sixfold compared

with a conventional plasma coating, as a result of the improved bond between the coating and the substrate.<sup>22</sup> A similar laser-plasma hybrid spraying system has been applied to deposit  $Y_2O_3$  stabilized  $ZrO_2$  thermal barrier coatings, with modified crack system and pore connectivity leading to a significantly decreased permeability in the produced coatings compared with laser posttreated coatings. Therefore, combined laser and thermal spray processes are promising for depositing denser coatings, with much increased processing efficiency, to achieve improved structure integrity and performance.<sup>23</sup>

#### 4.09.3.4 Laser Melt/Particle Injection

Laser melt/particle injection (LMI) can be considered as a special form of LC, which is aimed at producing a metal-matrix composite layer on top of a substrate. The laser beam melts the substrate locally while particles of additional material with a high melting temperature, usually ceramics, are simultaneously injected. Another version of LMI uses a laser beam to melt coaxially fed metallic powder and simultaneously inject ceramic particles into the melt pool. These particles are trapped when the melt pool rapidly solidifies after the laser beam has passed. Unlike LC, in LMI, the interaction between ceramic particles and laser beam is limited so that the ceramic particles remain mainly in the solid state, but with partial dissolution of the ceramic particulate into the melt pool, forming new phases at/around the interface between the particles and metal matrix.

MMC coatings are normally used for the improvement in wear performance. However, MMC coatings often have poor resistance to corrosion, and applications of such coatings in corrosive environment can be limited. Therefore, there is a need to achieve excellent wear performance with acceptable corrosion resistance. As described earlier, the corrosion properties of MMC coatings produced by thermal spraying are dominated by complex microgalvanic and interfacial mechanisms, as well as by oxide inclusions and porosity. However, it is possible to control the corrosion performance of LMI-produced MMC coatings by suitably adjusting the laser operating parameters to partially dissolve ceramic particles, to promote the formation of interfacial phases, and to eliminate other coating defects. For example, LMI-produced TiC-Ti-6Al-4V exhibits an excellent corrosion resistance in seawater after 1 month exposure.<sup>24</sup> In addition, MMC coatings of  $Al_2O_3$  particle injected Ni-Cr-Al-Hf produced by

LMI are possible candidates to meet the technical challenges of particular turbine components, such as the tips of turbine airfoils, requiring thermal stability, high temperature oxidation resistance, and wear resistance.<sup>25</sup> Compared with MMC coatings produced by thermal spray techniques, such as HVOF, LMI results in an improved corrosion resistance by (1) reducing the sharp composition gradient between the matrix and the hard phase through promoting some interdiffusion; (2) forming a uniform distribution of the phase and composition with a much lower number of defects such as porosity and microcracks in MMC coatings.

#### 4.09.3.5 Pulsed Laser Deposition

PLD is a thin-film deposition technique using high-energy laser pulses to vaporize the surface of a solid target inside a vacuum chamber and condensing the vapor on a substrate to form a thin film up to a few micrometers in thickness. Figure 2 shows a schematic diagram of a typical PLD process.

The main advantage of PLD derives from the laser material removal mechanism. PLD relies on a photon interaction to create an ejected plume of material from any target based on rapid explosion of the target surface region due to superheating. Unlike thermal evaporation, which produces a vapor composition dependent on the vapor pressures of the elements in the target material, the laser-induced expulsion produces a plume of material with stoichiometry similar to that of the target. Therefore, it is generally easier to obtain the desired film stoichiometry for multielement materials using PLD than with other deposition technologies.<sup>27</sup> On the other hand, the kinetic

**Figure 2** Schematic diagram of PLD process.<sup>26</sup>

energies of ablated particles are typically high enough to promote surface diffusion, but not so high as to induce bulk damage. Thus, PLD can create thin films of a wide range of materials, including metals, semiconductors, and insulators with excellent adhesion. Since PLD results in a high cooling rate during film formation, it is likely to form nanocrystalline or even amorphous alloy films. Some of the films have been applied as protective barriers in corrosive environments.<sup>28–30</sup> For example, amorphous Ta–Ni films produced by PLD offer extremely high corrosion resistance in both acid and alkaline solutions.<sup>28</sup> A 160-nm thick film of  $Y_2O_3$  deposited on Zn–22Al–2Cu alloy produces an improvement of up to 75% in corrosion resistance in aerated water of pH 4.5, compared with the alloy without the  $Y_2O_3$  film.<sup>29</sup> In addition, the PLD technique can be used to form alumina-stabilized zirconia films on fused silica substrate making for both corrosion resistance and thermal barrier purposes.<sup>30</sup>

Since it is possible to control microstructures in a wide range, from amorphous dense to microcrystalline porous, by properly selecting laser operating conditions, PLD offers significant advantages and manufacturing flexibilities for the formation of graded coatings for thermal and corrosion barriers, compared with other methods such as electron beam–physical vapor deposition (EB-PVD) and atmospheric plasma spraying (APS). A German National Science Foundation program has reported a successful

deposition of functionally graded thermal barrier coatings on Cu substrates by PLD to sustain extremely high thermal loadings in a hot gas environment.<sup>31</sup> A columnar–lamellar microstructure, with designed column size, graded profile of lamellae thickness and interface modification can be produced, to a large extent, by means of PLD using a combination of nano- and microsecond laser beam pulses.

#### 4.09.3.6 Laser Chemical Vapor Deposition

Laser chemical vapor deposition (LCVD) is employed to generate solid deposits on a substrate by laser beam-induced chemical reactions in a chemical vapor reactant. LCVD processes can be divided into two main categories: photolytic and pyrolytic, depending on the mechanism that activates the chemical reactions.

Photolytic LCVD, as shown in **Figure 3(a)**, utilizes photons of a laser beam to break chemical bonds within the reactive gases. The molecules either recombine or decompose to form a solid deposit on the surface of the substrate. Pulsed lasers in the ultraviolet wavelength, typically excimer lasers with photon energies of several electron volts, are used for photolytic reactions. The main advantage of photolytic reactions is the absence of high temperatures that may adversely affect the substrate or build up thermal stresses within the deposited layers. In pyrolytic LCVD, the energy of a laser beam is used to heat

**Figure 3** Schematic diagrams of LCVD (a) photolytic and (b) pyrolytic process.

the surface of a substrate to the temperature required for thermally driven chemical deposition, as shown in **Figure 3(b)**. Typically lasers with infrared wavelengths such as  $\text{CO}_2$ , Nd:YAG, and HPDLs, are used for such processes. Compared with the traditional thermal CVD, LCVD offers the significant advantage of avoiding the heating of the entire substrate to the reaction temperature.

Silica coatings on metallic substrates have been produced using an ArF excimer laser to photolytically induce the reaction between  $\text{SiH}_4$  and  $\text{N}_2\text{O}$ .<sup>32</sup> This technique is capable of producing complex silica coatings with graded density, thus efficiently solving the potential problem caused by thermal expansion coefficient mismatch between the metallic substrate and the coating. Protective coatings withstood thermal cycling and long-term corrosion tests at a temperature of  $450^\circ\text{C}$  without spallation. This excellent performance is associated with the reduced elastic modulus of the less dense coating in contact with the metallic substrate and the improved diffusion barrier provided by the fully dense silica deposited on top.<sup>32</sup> In addition,  $\text{Ta}_2\text{O}_5$  films with columnar, dense structures, prepared by KrF excimer laser CVD from tantalum-pentamethoxide ( $\text{Ta}(\text{OCH}_3)_5$ ), have been shown to reduce the corrosion current density of iron by six orders of magnitude, indicating that the dense LCVD- $\text{Ta}_2\text{O}_5$  coating was effective in increasing the corrosion resistance of an iron substrate.<sup>33</sup>

Although CVD has often been considered to be a slow process for the production of thick coatings, a laser CVD process has achieved high deposition rates for YSZ coatings with either a columnar structure (**Figure 4(a)**,  $230\ \mu\text{m h}^{-1}$ ) or a cone structure (**Figure 4(b)**,  $660\ \mu\text{m h}^{-1}$ ). At high deposition rates, a large number of nanopores are formed within grains

(**Figure 4(c)**), resulting in a thermal conductivity of  $0.7\ \text{W mK}^{-1}$ , which is almost the same as that of EB-PVD YSZ coatings. However, the nanopores in the laser CVD YSZ are relatively stable such that the thermal conductivity does not increase significantly after heat-treatment for more than 20 h at high temperatures of  $\sim 1000\text{--}1100^\circ\text{C}$ .<sup>34</sup> Laser CVD is also capable of forming other oxides, such as  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  coatings, at deposition rates  $\sim 1\text{--}2\ \text{mm h}^{-1}$ . The thick coatings, of more than several  $100\ \mu\text{m}$ , provides at high speeds by laser CVD may find many industrial applications in industries requiring corrosion and abrasion resistance.<sup>34</sup>

#### 4.09.3.7 Laser Surface Alloying

LSA is a process that is used to incorporate additional alloying elements into the surface of a component, by utilizing a laser beam with high power density to melt metal coatings and a portion of the underlying substrate. The typical thickness of the alloyed surface layer ranges from  $1\ \mu\text{m}$  to  $2\ \text{mm}$ . The thickness and the composition of the treated surface can be adjusted by controlling the laser power intensity and the interaction time. Due to the high cooling rate associated with LSA, nonequilibrium phases and supersaturated solid solutions can be readily achieved. LSA processes may be divided into two classes, namely, thin-film alloying and thick-layer alloying.<sup>35</sup>

The thin-film alloying process involves the use of short energy pulses (width range from some nanoseconds up to a few microseconds). The typical alloyed thickness is a few micrometers. The mixing process is based on a diffusion mechanism of mass transfer, with cooling rates of up to  $10^{11}\ \text{K s}^{-1}$ , leading to a strong decrease of the alloying elements' concentration with

**Figure 4** Cross-section of YSZ coatings prepared by laser CVD at a deposition rate of  $230\ \mu\text{m h}^{-1}$  (a),  $660\ \mu\text{m h}^{-1}$  (b), and nanostructure of the YSZ coatings (c).<sup>34</sup>

the increase of the depth in the modified layer. The thick-layer alloying process involves the use of either energy pulses of duration from 1 up to 20 ms or CW radiation, resulting in cooling rates of  $10^4$  to  $10^6 \text{ K s}^{-1}$ . The typical alloyed thickness is in the range of 0.1 mm to a few millimeters. The mixing process within the melt pool is mainly controlled by a convective mechanism of mass transfer. Therefore, the chemical compositional homogeneity of the melted layer can vary from relatively uniform to highly nonuniform, depending on the turbulent stirring effect within the melt pool driven by surface tension gradients that result from thermal gradients, that is, Marangoni effect. For metals, the convection speed is several orders of magnitude higher than the laser scanning speed, leading to a rapid homogenization. When the melting temperature of the alloying elements is considerably higher than the melting temperature of the substrate material, or when the alloying elements react with the melt pool material to form insoluble high melting temperature phases, alloying may be difficult.

A main characteristic of LSA is the possibility of producing an almost unlimited range of alloy composition for the surface layer, with fine and homogenized microstructures, tailor-made for the requirement. However, it is difficult sometimes for certain elements to be alloyed into certain material substrates. In selecting elemental combinations for LSA, attention needs to be paid to the relative melting temperature, vaporization temperature, and vapor pressure of alloying elements and substrate materials. Processing will be difficult if the added element vaporizes at a temperature that is lower than the melting temperature of the substrate material; for example, in LSA of Zn into a Cu substrate, since at 1 atm Zn boils at  $\sim 900^\circ\text{C}$ , while Cu does not melt until  $\sim 1100^\circ\text{C}$ .

The rapid cooling rate associated with LSA provides a unique opportunity for the generation of nonequilibrium alloys. The thickness and composition of the treated surface can be adjusted by properly choosing the type of laser and appropriately controlling the laser power intensity and interaction time. In LSA, the extent of solid solubility can be increased as a result of solute trapping arising from rapid rates of cooling. Therefore, more alloying elements can be retained in solid solution, with beneficial effects on corrosion properties or wear properties. There are other methods of producing nonequilibrium metallic alloys, using rapid solidification technology (RST), such as atomization, twin roll quenching, and melt spinning. However, in order to make an engineering component, the

materials must be consolidated, involving temperature and pressure cycles that can induce phase transition in a metastable material.<sup>2</sup> Therefore, laser processing has potential benefits for the generation of nonequilibrium materials for industrial applications.

Surface alloying of transition-metal elements, such as Cr, Ni, and Mo, has been applied on low-carbon steel substrates for corrosion protection. For example, LSA of Cr into mild steel produces a uniform Cr distribution in the alloy layer, and consequently, a decrease in the critical current density required for passivation and a decrease in the passive current density in the passive range.<sup>36</sup> In addition, LSA of Mo into 304 stainless steel increases in the critical pitting potential on potentiodynamic polarization in 0.1 M NaCl solution. The critical pitting potential for surface alloys containing 3% Mo is comparable with that of bulk 316 alloy, while surface alloys containing 9% Mo indicate no breakdown up to the oxygen evolution potential.<sup>36</sup> In addition, surface alloys rich in Ni–Mo produced by LSA of 304 stainless steel substrate result in a pitting resistance above that of AISI 316 stainless steel.<sup>37</sup> Fe–Cr–Ni–Mo–C surface alloys with different compositions can be produced on carbon steel.<sup>38</sup> The pitting potential of the Fe–18.7Cr–6.3Ni–3.8Mo–0.14C laser surface alloy is  $\sim 200 \text{ mV}$  higher than that of AISI 316 stainless steel and Fe–23.2Cr–7.3Ni–4.7Mo–0.13C laser surface alloy does not suffer pitting corrosion in anodic polarization tests in 3% NaCl.

LSA of nonferrous substrates has been applied for the improvement in corrosion properties. LSA of Al + Mn into a Mg alloy (MEZ) produces an alloyed surface consisting of dendrites of Al + Mn and Al + Mg, which significantly reduces the corrosion rate in 3.56 wt.% NaCl solution to 250 mpy, compared with 1520 mpy of the MEZ substrate. This improved corrosion resistance was due to the presence of  $\text{Al}_2\text{O}_3$  and  $\text{Mn}_3\text{O}_4$  layer on the alloyed surface, while the microhardness of the alloyed zone was enhanced up to 1250–350 VHN, compared with 35 VHN for the substrate.<sup>39</sup> LSA of Zircaloy-4 with niobium (Nb) significantly improves the resistance to localized corrosion in a chloride solution at  $80^\circ\text{C}$  due to the combined effects of a rapidly cooled, fine microstructure and the Nb alloying. However, it should be noted that the corrosion resistance of such an alloyed surface is reduced in steam at  $400^\circ\text{C}$ .<sup>40</sup>

LSA is a potential option for the improvement in the high temperature oxidation resistance of high temperature alloys. The high temperature oxidation resistance of laser-surface-alloyed Incoloy-800H with

Al is significantly improved at 1000 °C in air, due to the formation of an Al-rich layer close to the surface, which acts as a barrier against oxygen diffusion into the bulk.<sup>41</sup> In a similar way, LSA of Incoloy-800H with Al and Si improves the resistance to metal dusting.<sup>42</sup>

When LSA is used for thin-film alloying by use of excimer lasers, it provides a unique opportunity to produce concentrated alloying elements extending to depths of submicrometers to a few micrometers, without bulk heating or the requirement of a vacuum. A typical example is LSA of 50- $\mu\text{m}$  thick Ti foil with Pd layer of 310-nm thick, using a KrF excimer laser.<sup>43</sup> Using this technique, it was possible to form homogeneous surface-alloy regions by rapid diffusion and intermixing, and demonstrate a major improvement in the corrosion resistance in 0.1 M  $\text{H}_2\text{SO}_4$  solution at 80 °C, as shown in **Figure 5**, due to the shifting of the potential to the region of passivity of titanium. Such Pd-alloyed Ti foils have been of interest for increasing the life of titanium foils that are used as electron-transparent windows in the removal of  $\text{SO}_2$ ,  $\text{NO}_x$ , and volatile organic compounds from flue gas by EBs.

**Figure 5** Corrosion morphology of untreated titanium foil (a) and laser-alloyed with Pd after immersion in  $\text{H}_2\text{SO}_4$  solution (b) at 80 °C.<sup>43</sup>

Laser gas nitriding (LGN) is a special form of LSA by laser melting of a metal surface in a nitrogen gas environment to form a nitride layer on the irradiated surfaces by chemical reactions. Many metals, including iron, carbon steels, stainless steels, and aluminum alloys, can be nitrided by lasers. These layers are metallurgically bonded with the substrate and have better interfacial properties than those produced by other nitriding techniques such as PVD, CVD, and ion implantation. Depending on the type of laser, the typical depth of nitrided surface layers can be in the range of a few microns or up to a few hundred microns. In the LGN process, a major problem to be addressed is cracking. There are two types of cracks on laser nitrided Ti-6Al-4V surfaces: (1) macrocracks induced by the accumulation of tensile stresses during the laser melting process; and (2) microcracks related to the inherent brittleness of TiN.<sup>44</sup> However, such cracks can be eliminated by proper selection of laser operating conditions, such as energy level, pulse width, traverse velocity, and gas environment (e.g., diluted nitrogen gas). **Figure 6** shows a typical example of LGN of Ti-6Al-4V alloy, using a Nd:YAG laser with a pulse width of 200  $\mu\text{s}$ .<sup>45</sup> In cross sections, the microstructures mainly consist of an outer thin continuous layer of TiN, followed by a region of nearly perpendicular TiN dendrites, and an intermixture region of small dendrites and large needles of nitrogen-enriched  $\alpha$ -Ti phase. The density of TiN dendrites decreases gradually toward the interface between the nitrided layer and the substrate. An improvement in pitting corrosion behavior in 3.5% NaCl solution, associated with the presence of the TiN coating, can be achieved.

When an excimer laser is used for nitriding, the mechanism of formation of the nitrided thin-films

**Figure 6** Typical cross-sectional microstructure of laser nitrided Ti-6Al-4V surface.<sup>45</sup>

differs from that with other types of lasers. In the excimer laser nitriding process, the laser beam is focused on an alloy surface in a chamber containing nitrogen gas. At each pulse, the laser-surface interaction leads to metal heating and vaporization. Vapor plasma expands from the surface and a shock wave dissociates and ionizes nitrogen. It is assumed that nitrogen from the plasma in contact with the surface penetrates to some depth, to form a nitride layer several micrometers thick.<sup>46</sup> For example, excimer laser nitriding of  $\text{AlSi}_7\text{Mg}_{0.3}$  alloy produces an AlN (columnar microstructure) top layer (200–500 nm thick) standing on an AlN (grains) in the alloy diffusion layer.<sup>46</sup> Excimer LSM of aluminum alloy 6013 under nitrogen atmospheres forms AlN– $\text{Al}_2\text{O}_3$  films, which are barriers against corrosion in 3.5% NaCl solution as demonstrated by a reduction in corrosion current density of three orders of magnitude compared with the untreated alloy.<sup>47</sup> Excimer LSM of an Al-2009/ $\text{SiC}_w$  composite in nitrogen gas presents an improved corrosion resistance in 3.5% NaCl solution, due to the formation of AlN in the laser-modified layer. In addition, the reduction of both the

number of SiC whiskers, caused by excimer laser ablation, and the amount of Cu-bearing compounds in the laser-modified layer were also attributed to the improvement in corrosion performance.<sup>48</sup>

#### 4.09.4 Advantages and Limitations of Laser Applied Coatings

**Table 1** summarizes the laser applied coating techniques introduced in this chapter.

Since a laser generates extremely concentrated beam energy, laser-applied coatings offer significant advantages over more conventional surface engineering techniques. The laser techniques can be used to selectively modify surface composition and microstructure without affecting surrounding material properties and causing thermal distortion. Hence, these processes are applicable to processing of critical regions of a component. In addition, a unique advantage of laser coating techniques is the rapid cooling rate, which enables the formation of amorphous or microcrystalline surfaces, modification of

**Table 1** Summary of various laser applied coating techniques introduced in this chapter

Coating techniques		Coating thickness	Coating materials	Type of lasers
Laser cladding		Thick-layer (50 μm to 2 mm)	Metallic alloys; ceramics	CW CO <sub>2</sub> , CW Nd:YAG, HPDL
Laser melt/particle injection		Thick-layer (a few hundred micrometers to 2 mm)	Metal matrix composites	CW CO <sub>2</sub> , CW Nd:YAG, HPDL
Laser surface remelting (laser sealing; laser glazing) of thermal sprayed coatings		Fully or partially melting (melt depth greater than/equal to or less than thermal sprayed coating thickness)	Metallic alloys; metal matrix composites; ceramics	CW CO <sub>2</sub> , CW Nd:YAG, HPDL
Laser-assisted thermal spray		Thick-layer (50 μm to 2 mm)	Metallic alloys; metal matrix composites; ceramics	CW CO <sub>2</sub> , CW Nd:YAG, HPDL
Pulsed laser deposition		Thin-film (up to a few μm)	Metallic alloys; ceramics.	High energy pulsed lasers with ns pulse width, e.g., Excimer laser.
Laser chemical vapor deposition	Pyrolytic	Thin to moderate films (a few micrometers to a few hundred micrometers)	Metallic alloys, ceramics.	CW CO <sub>2</sub> ; CW Nd:YAG, HPDL
	Photolytic	Thin-film (up to a few micrometers)	Metallic alloys	Excimer laser
		Thick-layer (up to 2 mm)		CW CO <sub>2</sub> ; CW Nd:YAG; HPDL
Laser surface alloying		Thin-film (up to a few micrometers)		Pulsed Nd:YAG laser with ns pulse width; Excimer laser
Laser nitriding		Thick-layer	Metal nitrides	CW CO <sub>2</sub> , CW Nd:YAG; HPDL
		Thin-film		Pulsed Nd:YAG laser with ns pulse width; Excimer laser.

grain size and orientation, and control of inclusion morphology and distribution for improved surface microstructure at both the micro and macro levels. For thick coatings, laser techniques produce relatively pore-free surfaces compared with thermal spray coatings, which are integral to the substrate, and thereby eliminate the problem of debonding. For thin-film deposition, laser processing penetrates to greater substrate depths compared with ion beam treatments, which may result in a longer lifetime of the coatings.

On the other hand, a laser beam with sufficient energy density for coating processes has a limited size. Therefore, a laser-applied coating technique is less efficient than other conventional methods like thermal spraying, in terms of coverage rate; in addition, coverage of large area components by laser-applied coatings requires overlapping of individual tracks. This overlapping process could result in an inherently nonuniform microstructure in the treated surface due to the reheating of a small portion of the previous track. Such microstructural changes may or may not have significant influence on corrosion properties, depending on coating materials.

Generally, laser coating techniques, except PLD, require no vacuum conditions, thereby providing substantial manufacturing flexibility. They provide chemically clean, noncontact, possibly remotely operated procedures that can be automated and integrated into other conventional production processes. Therefore, laser-applied coatings have become the preferred choice in many applications. Applications of laser-applied coating techniques can be limited to small areas, complex shapes, and high value/high cost items. However, the interest in laser-applied coatings, especially LC, of large components is increasing. With reductions in the cost of laser power, increased reliability and output power, and capacity of fiber delivery systems, coatings over large areas have become cost effective. These improvements have enabled lower-value items to benefit from laser-based coating techniques. For example, the power generation industry has begun to use LC of boiler tubes and water walls in steam generators, which can be justified in terms of the environmental improvement resulting from the reduced use of chromium. In addition, the development of an effective combination of laser processing and conventional thermal spray systems has provided a new opportunity for depositing dense coatings with improved structural integrity and performance on large surface areas at acceptable process efficiencies for industrial applications.

As with all laser-based processes, a lack of familiarity with the process may be an obstacle to industrial application. However, as more sophisticated operating systems become available, in which computer-generated models are integrated with automated beam and alloy delivery, the scope of applications of laser-applied coating is increasing considerably.

### Glossary

**Thinners** A low-viscosity liquid, commonly a solvent, which is added to paint prior to coating application in order to reduce its viscosity and permit easier and more rapid paint application, especially by spraying.

**Transfer efficiency** The ratio, as a percentage, of liquid paint to the quantity of organic coating that is applied to the surface. This can approach 100% for manual brush and roller application but is usually in the 40–70% range for spray application.

### Abbreviations

**HVLP** High velocity low pressure

**ICATS** Industrial coatings applicator training scheme

**ICorr** UK Institute of Corrosion

**VOC** Volatile organic compounds

### 4.10.1 Introduction

Paints and organic coatings may be applied by many methods,<sup>1,2</sup> and it is not possible to consider all of them in detail in a chapter of this size. The main emphasis has been placed, therefore, on the methods of paint application used most commonly to protect constructional steelwork from corrosion<sup>3,4</sup> at either the fabrication stage or when the maintenance painting is required.

### 4.10.2 Methods of Applying Paints and Coatings

There are four main methods of applying paints and coatings for corrosion protection:

- by spreading, for example, by brush or roller;
- by spraying, for example, by air-assisted spray, airless spray and electrostatic spray;
- by dip coating and flow coating;
- by electrodeposition (this method is considered elsewhere in this volume).

For most steel fabrications and structures, protective coating systems are applied by spray. Application by brush is used to a much lesser extent, mainly for minor coating repairs during maintenance painting programs. At factory work, pipes and small fabrications may be dip coated and, during maintenance, some small, relatively inaccessible tanks, for example, may be flow coated.

#### **4.10.2.1 Brush Application**

The application of paints by brush is labor-intensive and time-consuming. Success depends to a very large extent on the quality and suitability of the brush, the rheological properties of the coating, and the diligence of the painter. Industrially, therefore, more rapid and efficient methods of paint application are now preferred.

Brushing is still seen, however, as a very suitable method of application for maintenance painting of small areas, for stripe coating of sharp edges and for coating awkward or restricted areas where spray application would be either difficult, or may not be permitted for reasons of health and safety.

When paints are applied by brush, there is minimal wastage and, usually, very little contamination of adjacent areas. A transfer efficiency approaching 100% is possible. Brushes can also be cleaned easily after use and, thereby, maintained in good condition.

The shape, length, and mechanical properties of the bristles of a paint brush determine its potential performance. The bristles must be capable of holding sufficient paint to allow coverage of a reasonable area from each loading. Bristles made from Chinese hog are excellent in this respect and continue to be favored by many painters, over brushes made with synthetic bristles of nylon or polyester fiber.

The size and shape of a paint brush determine its suitability for a particular coating task. Wide, flat brushes, for example, are most appropriate for coating large flat surfaces. Small round or oval brushes are most appropriate for specialist tasks, such as the coating of more complex surfaces with bolt heads and possible crevices. The action of brushing paint into relatively inaccessible spaces forces the coating into contact with the surface and promotes the wetting needed for full coverage and subsequent good adhesion.

Brushing is not a suitable method of application for paints, which dry rapidly by solvent evaporation, such as vinyl coatings, for example, as the viscosity of the applied film can increase rapidly and may quickly become difficult to apply satisfactorily to give an even film, free from brush marks.

#### **4.10.2.2 Roller Application**

The application of paints manually by roller to large, flat areas can be up to four times faster than coating the same area with a brush. Brushes may still be needed, however, to coat corners and edges satisfactorily. As cleaning of the roller after use can be time-consuming, industrial painters will often discard some types of roller cover (the cheaper ones), without cleaning: these thus become effectively 'single-use' items. The roller cover types used most commonly are mohair, lambswool, nylon and polyester. The cover material selected and the length of the nap will be determined usually by the type of coating to be applied and the surface finish required. The roller itself must be resistant chemically to solvents in the coating and also to any thinners used.

While most hand rollers are loaded simply by dipping them into a tray of paint, it is possible also to mechanize the procedure and feed paint to the roller with an electric pump. The inlet to the pump, typically a flexible tube with a filter on the end, is immersed in the can of paint. Flow to the roller is then controlled by a finger valve on the applicator handle. It is possible to achieve very high transfer efficiency, often better than 95%, when paints are applied by roller.

#### **4.10.2.3 Air Atomized Spray Application**

Air atomized spray guns were the first type of spray guns to be used commercially. They allow paint to be applied up to eight times more quickly than by brush, with better control and uniformity of film thickness. Losses of paint are, however, considerably higher than those incurred by either brush or roller application and considerable skill is needed to produce quality finishes at an economic cost.

In air atomized spray application, also known as conventional spray application, compressed air is used not only to atomize the paint, but also to propel it towards the surface to be coated. As the paint passes through the orifice of the fluid nozzle, it is mixed with compressed air and atomized at pressures, typically between 0.2 and 0.4 MPa.

Paint may be fed to the spray gun by gravity, by suction or by compressed air from a pressurized container. In the gravity feed system, the paint is placed in a cup on top of the spray gun and is fed to the nozzle by gravity. Gravity fed guns are ideal for small spray painting tasks, as they can be cleaned relatively easily after use. In the suction feed system,

the paint is contained in a cup fixed to the underside of the gun and is drawn upwards into the gun as a result of the partial vacuum created at the nozzle by the flow of compressed air. The most common conventional spray gun, when used to paint large areas, relies on the paint being fed to the nozzle by compressed air, via a hose from a pressurized container.

Over-spray and bounce back are the two main disadvantages of conventional air atomized systems. Transfer efficiency is relatively poor and is, typically, between 30 and 45%. Overspray occurs when the paint misses the object being coated. The extent of overspray will depend on the size and shape of the object. It is influenced also by the spraying pressure, spraying distance, skill of the sprayer, and characteristics of the paint itself. Overspray may often contaminate other nearby surfaces on which it settles.

Bounce-back is a consequence of the high pressure of compressed air needed to atomize the paint. The air 'bounces' off the component, or the surface being sprayed, and, in doing so, creates an air barrier to the paint sprayed subsequently. The result is a fog or mist of the atomized paint, a characteristic feature of this method of application.

#### 4.10.2.4 High Volume Low Pressure (HVLP) Spray Application

HVLP spray application is not a new process, but a novel spraying technique that has been developed further commercially to improve transfer efficiency and reduce the emission of volatile organic compounds (VOCs) to the environment, when solvent-borne coatings are applied by an air atomizing spray method. HVLP spray guns have now replaced conventional air atomized spray guns for many paint finishing operations. The HVLP spray gun still relies on air atomization but uses higher volumes of air at low pressures. Paint is delivered to the nozzle of the gun under pressure and is then atomized by this low-pressure air. In order to accommodate the larger volumes of air required, the air passages in the spray cap of the HVLP gun are much larger than those in a conventional spray gun.

HVLP spray application systems were developed originally in France in the 1950s. The earliest systems used a turbine to generate the high volumes of low-pressure air required. They were self-contained, requiring only an electrical supply to power them. Today, most HVLP spray guns use standard compressed-air systems for motive power. In the compressed-air HVLP spray application system,

the air entering the gun is at a pressure of around 0.5 MPa. It is converted to low pressure, typically 0.05 MPa, inside the gun through either a series of valves and chambers designed to promote rapid expansion of the compressed air, or by means of a specially designed baffle located near the tip of the gun. At the low pressures which result, the forward velocity of the spray pattern is reduced considerably, in comparison with the forward velocity of atomized paint from a conventional compressed-air spray gun. As a consequence, there is significantly less overspray and substantially less bounce-back because of the lower velocity of the paint. The combined benefit is a much improved transfer efficiency of at least 65%. Speed of application is comparable with that of conventional air atomized spraying.

#### 4.10.2.5 Airless Spray Application

This method of spray application is very different from the conventional techniques described previously. In airless spray equipment, the paint is not atomized by air. A fluid pump is used to force paint at high pressure through a fluid hose to the gun. Atomization is achieved by the release of highly pressurized liquid paint through a small orifice in the spray tip. Fluid nozzle sizes range, typically, in diameter from 0.03 to 0.15 mm. On exit from the small orifice in the spray tip, the paint atomizes into a cloud of ultrafine particles which then move forward slowly towards the surface to be coated. The slowing down is caused by the resistance of the atmospheric air and the cloud of ultrafine particles impacts on to the surface at a relatively slow speed, in comparison with conventional spray application. As there is no overspray and no bounce back, a transfer efficiency of well over 50% can usually be achieved. Penetration of the paint into crevices and recesses is good and, in the absence of entrained atomizing air, little or no solvent evaporation occurs during the spraying process. As a result, the subsequent flow out of liquid paint on the surface of the work piece is good.

Typically, the fluid pumps used with airless spray equipment have multiplication ratios of 48:1 or 60:1. This is the ratio of fluid output pressure to air input pressure. As the fluid output pressure at the spray tip can be of the order of 27 MPa, airless spray guns can deliver paint very rapidly and enable large areas of steel structures, for example, to be coated quickly. A surface area of 300 m<sup>2</sup>, for example, can be coated in 1 h. The skill and experience of the sprayer will always determine the evenness of coverage and the

final quality of the finish. Careful choice of tip size and spray width (the 'fan') is critical to success and the guidance given by the paint manufacturer on the technical data sheet for the coating product to be sprayed needs always to be observed.

It is important to note that airless spray guns can be dangerous in unsafe hands because, close to the nozzle, the paint being delivered is at a very high pressure. To prevent operators from carelessly, in effect, 'injecting' them with paint, all airless spray guns are fitted with tip safety guards.

#### **4.10.2.6 Air-Assisted Airless Spray Application**

As its name implies, air-assisted airless spray is a hybrid of airless spray application and conventional air atomized spray application. The purpose of introducing a compressed air supply is to aid atomization and improve fan pattern shaping, without creating excessive bounce back. Air-assisted spray application requires a lower fluid pressure than airless spray application; typically between 3 and 10 MPa. Spray tips with larger nozzle orifices can, therefore, be used. Transfer efficiency is typically between 65 and 70%.

The major difference in construction between an air-assisted airless spray gun and an air atomized spray gun is the atomizing tip. The air-atomizing tip has a fluid nozzle and an air cap which delivers a ring of atomizing air around the fluid nozzle. In addition, two fine jets of air are emitted from ports in small 'shoulders' on each side of the tip. The purpose of these two air jets is to break up any large droplets of paint, formed as a consequence of lowering the fluid pressure, and complete the atomization.

#### **4.10.2.7 Heated Spray Application**

Both conventional air atomized spray and airless spray equipment can be used to apply paint coatings which have first been heated to 60–80 °C. Raising the temperature of the paint to this level lowers its viscosity (by as much as two-thirds of its viscosity at ambient temperature), aids flow and reduces drying time. If the heated paint is applied by the conventional air atomized spray, for example, the air pressure needed can often be halved and transfer efficiency improved. If the heated paint is applied by airless spray, a lower fluid pressure is needed and the efficiency of the equipment as a whole is improved.

More sophisticated heated spray application equipment has been developed in previous years to apply some solvent-free two-pack coatings, notably epoxies. In this type of spray equipment, base and curing agent are heated separately, pumped to the gun and then mixed either with a small agitator in the gun itself or, with arguably less efficiency, in the turbulence of the emerging spray. Accurate metering of the two components is essential whichever mixing method is used and this is achieved with the aid of carefully calibrated pumps. Twin-feed heated airless spray equipment is expensive and needs always to be maintained well. Specially trained operators are usually required.

#### **4.10.2.8 Electrostatic Spray Application**

This application method takes advantage of electrostatic attraction to improve transfer efficiency. When paint droplets are passed through a powerful electrostatic field, they become charged. If the work piece is earthed, the charged droplets are attracted and will coat not only the front face of the work piece but also some of the back face. The extent of coating 'wrap round' achieved, will depend on the size of the work piece and its depth.

In most manual electrostatic spray guns, the power pack delivers, typically, a voltage of 60–85 kV at a current of 150  $\mu$ A to a point electrode close, but external to the spray head. The air in the immediate vicinity of the spray head becomes highly charged and the charge is transferred partially to the atomized paint droplets, as they pass through. It is also possible for paint to be charged directly by an electrode fitted inside the gun itself. For electrostatic spray guns with internal charging, an operating voltage of 30 kV is typical.

All of the spray application methods, which have been described above, can benefit from the addition of electrostatic charging. Transfer efficiency is improved throughout, often by as much as 20%. For steelwork, the main advantage of applying paints by electrostatic spray is gained when long runs of perimeter-fencing or similar 'open' structures need to be coated.

Electrostatics add significantly to the cost of the spray equipment and, as a consequence of the charge imparted to the spray droplets, only relatively thin coatings can be applied easily. Electrostatic spraying methods are used most commonly for industrial finishing operations, in particular the automated application of coating powders.<sup>5</sup>

#### 4.10.2.9 Dip Coating

Small fabrications, which may be both difficult and time-consuming to paint satisfactorily by brush and difficult to paint by spray, can often be painted more effectively by dipping. Steel pipes are also often coated in this way. Specially formulated liquid paints are needed for dipping tanks and, in use regular checks on the viscosity of the paint are required. Additions of solvent have to be made from time to time to adjust the viscosity of the paint to its specified level. Dip coating is a rapid process in which all accessible areas are coated at one time. However, controlled withdrawal of the work piece from the bath is critical to success to minimize the presence of 'runs' and sags in the finish. Sharp edges, if present in the work piece, will not be coated to the same thickness as the main surfaces.

#### 4.10.2.10 Fluidized Bed Coating

Thermoplastic coating powders can be applied, at works, to heavy metal pipes by a somewhat different dipping method called *fluidized bed coating*.<sup>5</sup> The coating powder to be applied is loaded on a porous membrane near the bottom of the dip tank and air, at low pressure and in high volume, is passed upwards through the membrane to 'fluidize' the powder. Low-pressure air blowers are used for this purpose. The work piece is first heated to a little above the melting point of the coating powder. It is then lowered into the fluidized bed and subsequently withdrawn. The dwell time, which may range from a few seconds to several minutes, as required, will determine the thickness of coating achieved. If the coating powder being applied is a thermosetting type, the coated work piece will need then to be postcured in an oven. Very thick powder coatings can be built up on heavy gauge steel pipes very satisfactorily by this relatively simple application method.

#### 4.10.2.11 Flow Coating

In a variation on the dipping process of paint application, small fixed items of intricate shape are often best recoated on site by flow coating. Electrical transformer radiator tanks, for example, can be recoated most effectively in this way.<sup>3</sup> Paint is poured into a temporary tank built around the item and allowed to flow into any corners and crevices. The excess paint is then drained; if still clean, can be used again.

Specially formulated paints are again required. For the process to be successful, very thorough precleaning, usually with solvent, is essential.

### 4.10.3 Application Conditions

The main environmental conditions which can have a bearing on the success of any paint application method are temperature, relative humidity and ventilation. The paint itself needs also to be in good condition and within shelf-life. Temperature will influence the viscosity of the paint, rate of evaporation of solvent (which may be water), drying time, and curing time of the coating. Application of paints at low ambient temperatures to cold surfaces will extend drying time, curing time and increase the overcoating interval. Conversely, application of paints at high ambient temperatures will increase solvent evaporation, drying time, curing time and may shorten the overcoating interval.

The level of moisture present in the air when paint is being applied is equally important. If the relative humidity is too high, unwanted condensation may occur on the surface of the workpiece. Any moisture on the surface may interfere with paint adhesion and may also interfere with the curing of some two-pack chemically cured coatings. Conversely, if the coating being applied relies on the presence of moisture in the air to cure it, then low relative humidity can also become a problem. Good ventilation is always desirable, as it will aid initial drying of the coating and help to maintain air safety in the working environment.

### 4.10.4 The Applicator

The final outcome of any paint application process will be determined, to a great extent, by the skill and diligence of the applicator. In 2005, the UK Institute of Corrosion (ICorr) launched an Industrial Coating Applicator Training Scheme<sup>6</sup> (ICATS). The scheme, which is operated through the ICorr trading subsidiary Correx Ltd., is a comprehensive structured program for the training, certification and registration of industrial surface preparation and coating operatives.

**4.11.1 Introduction**

How does one formulate/design a corrosion protective coating? This is the key question that this chapter seeks to answer. Before 1900, the process of formulating/designing organic coatings was an art form, similar to that of developing food recipes. Around the dawn of the twentieth century, awareness of natural oil film formation and crosslinking began to be developed, as well as the optical and physical effects of pigmentation. (It is noteworthy, in the context of the timing of coating science development, that research and development on paints and coatings began formally at North Dakota State University in 1905, and the authors' academic department is a direct descendant of this coatings research program.) The first science impacting directly on coatings was chemistry, and later chemistry's great twentieth century offshoot, polymer chemistry and science. Since then, optical physics, composite science, and materials science<sup>1</sup> have all contributed to the science and design/formulating of organic coatings. One of the most important functions of organic coatings is to protect substrates of all types. When the substrate is a metal, the primary function of the coating is to protect the metal substrate from corrosion. Most OEM coatings, whether for automobiles, aircraft, or metal furniture, have the primary function to protect against corrosion. The entire class of coatings known as 'industrial maintenance' coatings have corrosion protection as their primary purpose. The least expensive method, in reality, of protecting an object against corrosion is to coat the object with a film of the proper organic coating system. Consider making a car entirely from stainless steel versus producing it as a painted steel frame, galvanized steel sheet outer system, and plastic composite bumper system that is the modern car. From this, one easily sees the efficiencies in cost and appearance in using organic coatings for protecting against materials degradation.

The objectives of this chapter are as follows:

- describe briefly the material components of coatings;
- describe how the performance requirements of a corrosion protective coating are specified;
- describe how one designs a corrosion protective coating;
- describe briefly how a corrosion protective coating is tested to determine whether it meets its performance requirements.

While pursuing these objectives, we have to include general discussions concerning the component materials of a coating, specifying coating performance requirements, the process of the coating design, and the testing of coatings. As much as possible, the focus of these discussions will be on corrosion protective coatings, and the emphasis will be on considerations of the rapid and efficient design of such coatings.

All the components of a corrosion-protective coating system must function properly for it to provide all the elements of physical protection and optical performance that it was designed to provide. To ensure proper coating system functions over its desired lifetime, one must have the capacity to define, measure, and evaluate the properties that determine these functions in use. For corrosion-protective organic coatings, the desired properties can be summarized as mechanical/chemical protection of the metal substrate, with acceptable appearance parameters. This is easily enough said, but difficult to achieve in practice. There are many properties one can measure in a corrosion-protective coating system. Indeed, the present cohort of designers and users of these systems are uncertain about which set of measurements to choose. They seek the set that will give the maximum amount of pertinent information with least effort and expense. The *sine qua non* of such properties is yet to be determined, but the current 'best practice' thinking among the coating-science community focuses on adhesion, solvent resistance, corrosion protection, and appropriate optical performance over its lifetime. It also takes into account the effects of UV exposure, hot and cold organic fluids, seawater, humidity and temperature cycles, mechanical stress, and abrasion. All these must be considered while choosing the tests/results protocol that the coatings/pretreatment must undergo to be 'fit for use.' We discuss the current thinking on the measurements/exposures for corrosion protective coatings as well as the accuracy/validity they provide in practice. We also discuss spectral, optical, and electrochemical testing of coatings system properties and their changes in simulated and field exposure. The differences between test performance and real use performance are considered, especially with respect to film application uniformity and film damage<sup>2</sup> (taken with some changes from the introduction/abstract of Bierwagen and Tallman).<sup>2</sup>

One of the overriding themes of this chapter is that organic coatings, especially those for corrosion protection, are random two-phase composite materials and must be specified, designed and tested as such.<sup>3</sup> As clearly stated in Chapter 1 of *Random*

*Heterogeneous Materials*,<sup>4</sup> the proper way to interpret the behavior of pigmented organic coatings is as a random heterogeneous composite where the volume fraction of the pigment phase is a crucial measure of concentration of materials. This measure, known now in the coatings industry as the pigment volume concentration (PVC),<sup>3,5,6</sup> is the crucial measure of pigment concentration for the characterization and design of pigmented coatings. Another crucial measure of pigmentation for coatings formulation is the critical pigment volume concentration (CPVC). We discuss this in [Section 4.11.6.1](#).

#### 4.11.1.1 Materials Used in Coatings

In general, when considering liquid coatings, one chooses the materials comprising a corrosion-protective coating from the three classes of materials shown in [Figure 1](#). Many of the negative environmental impacts of coatings come from the solvents emitted during coating application and curing/drying. If one uses powder coatings, for example, the use of solvents is abandoned. One should note here, that in many dispersions, because of environmental considerations, water is a carrier liquid for a fine particle dispersion of polymer and pigment rather than a true molecular solvent for the coating. The resins are the organic polymer matrices of coatings; pigments are the solid, insoluble particles that assist the coating in supplying color and other functions, including protection of a substrate.

#### 4.11.1.2 Protection of Surfaces by Paints and Organic Coatings

[Figure 2](#) gives a general description of the methods by which one stops corrosion. A proper choice of substrates may accomplish some of these, but often, a coating is also used as a supplemental protection.

Corrosion-protective coatings work in three modes<sup>7</sup>: (i) barrier protection; (ii) cathodic/sacrificial protection (i.e., zinc rich coatings)<sup>8–10</sup>; and (iii) inhibitive/passivation protection (i.e., coatings formulated with partially soluble inhibitive pigments and/or additives). The latter two modes are what may be designated as 'active' protection, that is, a protection that is provided to the metal substrate in damaged areas of a coating by such processes as dissolution,

**Figure 1** Primary components of organic coatings.

mass transport, chemical reaction, and adsorption. Barrier protection is the passive mode, by which intact coatings provide protection to metal substrates, and is the protection provided by the reduction of the transport of materials, ions, or charge.<sup>11–13</sup> Barrier properties that are important for coatings are the resistance to the transport (small diffusion coefficients) of the chemical species of the corrosion reactions, which are in most cases  $\text{H}_2\text{O}$ ,  $\text{O}_2$ , and electrolyte ions.

#### 4.11.1.3 Unique Properties of Paints and Coatings for Corrosion Control

Coatings decorate and protect the substrate to which they are applied. One can summarize the unique features required in corrosion-protective organic coatings for the protection of metal substrates. Such a coating must have a combination of barrier, sacrificial and inhibition/passivation protection of the coating–metal substrate interface. For this protection to occur, the prime features of the painted metal system are as follows:

Dry film properties:

- A. Wet/dry adhesion-keeping coating in contact with the substrate under exposure conditions;
- B. Low ion, water, and oxygen permeability of the coating film – barrier effects;
- C. Low coating/film conductivity – minimize flow of current in local corrosion cells and stop ion and electron motion in film;
- D. Coating/film stability to its environment, stability to hydrolysis and UV radiation, thermal stability, etc.;

**Figure 2** Summary of modes of corrosion protection of metal substrates.

- E. Strong adsorption of coating to substrate interface – good wetting of the substrate by the coating system;
- F. Coating pigmentation for passivation/inhibition (chromates), sacrificial (Zn-rich coatings,  $A = 1$ ), or barrier ( $A = \text{PVC/CPVC} \cong 0.85$ ) coatings.

System properties:

- A. Good quality metal substrate and pretreatment;
- B. Coating film be applied uniformly in a defect-free manner to metal substrates of all shapes and sizes.

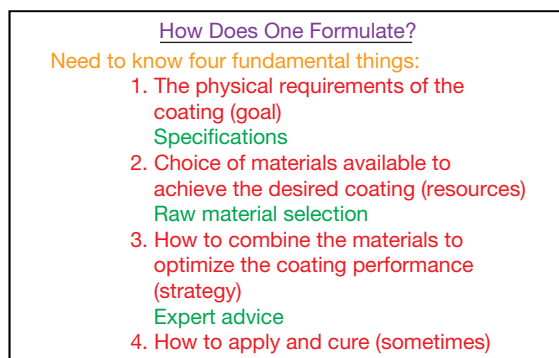

In this list, adhesion to metal substrates, strong absorption to metal substrates, and wetting of metal substrates are all unique features of organic systems, as they interact with metal–metal oxide surfaces. The ability to be applied uniformly with no defects is crucial to the performance of corrosion-protective coatings. This means that for corrosion protective coatings, the method of application is almost as important as the properties of the coating being applied. Each of these topics will be discussed in more detail below.

#### 4.11.1.4 Formulation as a Scientific Design Activity

The basics of coating formulation have been discussed often,<sup>14</sup> but the primary issues of designing a coating still remain the same. The complexity of the design process is quite extensive. This has been noted as a general issue of the design process, as well as specifically for coating designs (Figure 3).<sup>15,16</sup>

#### 4.11.1.5 Testing of Corrosion Protection by Paints and Organic Coatings and Feedback to Coatings Design

The final stage of coating design is the testing of the coating to determine whether it meets the design

**Figure 3** Schematic of multilayer coating system.

specifications. This is often done using standardized test methods (often from ASTM or SSPC) for measuring the obvious parameters such as color, density, and hardness.<sup>17</sup> The testing of corrosion performance is often much less of a standardized issue, and many of the ASTM Test Methods for Corrosion Protection by Coatings, including B117, have met with serious disagreement from many researchers in their application. Much of the work on the testing of coatings for corrosion protection has involved the use of electrochemical methods to supplement or even replace the more traditional subjective test methods still in use for this purpose.<sup>18</sup> This is discussed in more detail in subsequent sections.

As the coating is tested, many small incremental modifications of the original design are made to achieve the best combination of the properties that still satisfy the original specifications. The final design is thus a nonideal choice of materials, which optimizes the total performance, but is often less than optimal among the many physical and chemical properties of the coating.

#### 4.11.2 Overview of Corrosion Control by Paints and Organic Coatings

As stated earlier, there are several general routes by which paints and coatings protect metal substrates from oxidation/corrosion. More specifically, they provide barrier protection for the substrate, cathodic/sacrificial protection by metal pigments more reactive than the metal substrate, and inhibition/passivation of the metal substrate by dissolution/ion exchange/controlled release from pigments or additives in the coating. Coatings are applied to substrates largely to protect them from the corrosive environments in which they function. Therefore, one can say that the passive barrier function of coatings is the primary mode by which they protect substrates. The active corrosion protective functions of coatings, the release or dissolution of inhibitors, or passivating chemicals, and sacrificial protection, occur in most cases when the coating is damaged and then breached, or by defects in the coating application process, which give incomplete coverage to the substrate.

Most often in the use of organic coatings for corrosion protection, the total coating system is multilayered.<sup>2</sup> The first organic coating layer applied to the metal substrate, or as is often the case, over a thin inorganic pretreatment layer on the metal substrate, is often called the primer layer. This layer is that

portion of a coating system that most frequently contains the active components, metal pigments, or soluble pigments that give active functionality to the total coating system. The subsequent coatings on top of the primer often provide most of the barrier properties of the total system. For example, the multilayered coating system usually contains (at a minimum) a primer/pretreatment layer, primer, base coat, and top coat. The optical functions of the total coating system, such as hiding, color, and camouflage, are provided most often by the coatings applied over the primer.

##### 4.11.2.1 Barrier Protection by Coatings

It is known that the primary function of a corrosion-protective coating system is to be a barrier between the coating system and the environment. However, no coating system now in use stops completely the transport of oxygen, water, and ions to the coatings-metal interface. Barrier protection is the reduction of the transport of materials, ions, or charge to the surface of the metal substrate.<sup>11-13</sup> Barrier properties that are important for coatings are resistance to the transport (small diffusion coefficients) of the chemical species of the corrosion reactions, in most cases,  $\text{H}_2\text{O}$ ,  $\text{O}_2$ , and electrolyte ions usually  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ , and a mixture of cations such as  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{NH}_4^+$ , and  $\text{Ca}^{2+}$ . Along with these barrier properties, high resistance to the flow of charge, electronic and ionic, is also important, as has been observed by Mayne<sup>12</sup> and Funke.<sup>11</sup> The barrier properties of polymer and paint films are known to be increased by their exposure to various gases and liquids.<sup>13</sup> The exposure of polymer and paint films to solvents that plasticize them greatly increases the transport properties of these films if they reduce the effective  $T_g$  of the films below the temperature of film use. Also, the exposure of these films to aqueous electrolyte solutions causes many coating films to swell and develop conductive pathways not present in the film before exposure.<sup>19</sup> These also severely reduce the barrier properties of the coating.

Let us examine an idealized multilayered coating system of three layers as shown in Figure 4.

In most coating systems, the outermost layer, in this case Coating III, is the layer whose primary function is barrier protection. This means that the polymer of this layer has to reduce the transport of water, and of oxygen to a lesser extent, into the coating film, as well as prevent the movement of dissolved ionic species through the film. The coating

**Figure 4** Schematic of multilayer coating system.

polymers that achieve this best are those that are hydrophobic and resist photooxidation in exposure. Examples of these are exterior quality urethanes, fluorourethanes, and fluorocarbon-based polymers such as kynar. One should note that the interphase region between each layer in the coating is separately identified, because this region often performs in a manner superior to the bulk of the coating *vis à vis* resistance to transport. In a recent paper from this laboratory, the interfacial region was identified separately in an equivalent circuit description of a coating, and this enabled one to identify this region and its contribution to the barrier properties of the system.<sup>20</sup> The issue of the interfacial layer and its importance in coating design performance are described in detail in several references.<sup>3,21</sup>

The barrier properties of coatings can be estimated by the use of electrochemical impedance spectroscopy (EIS) and electrochemical noise methods (ENM).<sup>22–24</sup> The monitoring of the low-frequency impedance modulus and/or the electrochemical noise resistance with exposure time (either natural exposure or accelerated exposure),  $|Z(t)_{\text{lowf}}|$  or  $R_n(t)$ , have shown themselves to be very useful techniques for following the changes in coating performance in the field or accelerated testing. Measuring the diffusion of water into a coating by single frequency EIS measurements is also a powerful tool for monitoring aqueous diffusion in coatings.<sup>25</sup> This group of electrochemical techniques provides a strong set of measurement tools for examining the barrier properties of organic coatings over metal substrate. Permeability measurements for water and oxygen performed by the use of a film and a sensing device of a gravimetric measurement for the permeant have also been performed, for example, for water, weight change in a desiccant on the other side of a film. There is a considerable literature in this area.<sup>26</sup> Gravimetric measurement of water pickup by coatings can supplement the methods just described.

#### 4.11.2.2 Active Metal Pigmentation and Cathodic Protection

The other modes in which coatings provide corrosion protection are active modes. In the case of metal-rich coatings, the protection comes from the chemical activity, or oxidation of an active metal pigment to provide sacrificial, cathodic protection to a less active metal substrate. Metal-rich coatings provide protection for metal substrates in a unique manner. They provide cathodic protection to the underlying substrate through high volume concentration of a more reactive metal than the substrate.<sup>27,28</sup> At the later stages of their performance, the basic metal oxides created from the particulate metal in the coating help to generate a barrier and passivation protection. A general description of these coatings is that they are designed with high volume fraction of metal pigment particles (near CPVC) dispersed in a non-conductive polymer or inorganic matrix. They were originally designed in the late 1930s with particulate Zn in matrix over steel. As particle volume fraction is high enough to give almost complete particle-to-particle contact, when a coating is applied to a metal substrate, it provides sacrificial/cathodic protection to the substrate. In effect, Zn-rich coatings act as a galvanizing layer that can be applied *in situ* to metal objects that cannot receive a galvanizing Zn or Zn/Al alloy layer. Metal-rich coatings are most often used as a primer, with a decorative or functional top-coat, which mainly provides barrier protection. Metal-rich coatings need basic material research to enhance their design and function. North Dakota State University has been active in this area recently applying metal-rich methods to the protection of Al alloys and other metals more reactive than steel.<sup>29–31</sup> This work indicates that Mg-rich coatings can provide similar protection to aerospace Al alloys such as AA 2024 T-3. This is the first completely Cr-free (no Cr-based pigments or pretreatments) protection system that gives long-term protection to such alloys.

The protection of automobile steel sheet outer bodies by galvanizing was first introduced by Porsche in circa 1970, and has been extended to all types of automobiles throughout the world. In conjunction with cationic electrodeposition coatings at about the same time, galvanized sheet steel increased the corrosion protected lifetime of the automotive coating systems considerably. Pure Zn as well as Zn–Al alloys are the common metallic layers used to protect sheet steel.<sup>32</sup> The warranties in cars for perforation corrosion protection are now commonly about 10 years<sup>33</sup> and the automotive companies have current goals of 15 years of perforation protection with 10 years of cosmetic appearance protection. The use of Zn-rich coatings has always aimed at providing protection similar to the galvanizing metal layers used on sheet steel. A review of the production and properties of galvanized steels has been published fairly recently.<sup>34</sup> Further, the problems in edge protection by galvanized layers have been studied recently and remain some of the major problems in the use of galvanized sheet.<sup>35</sup>

In the original paper on Mg-rich coatings,<sup>29</sup> a summary of the performance of a Zn-rich coating was given and was utilized to design and predict the performance of metal-rich coatings in general. This summary is paraphrased as follows:

1. This class of coatings uses either organic or inorganic matrices, and is used mainly as a primer.
2. They are pigmented with particulate Zn, in either spherical, random shape, or flake form.
3. The PVC of the Zn pigment in the coating should equal or exceed the CPVC for the coating to properly provide sacrificial/cathodic protection to the underlying steel substrate. At or above the CPVC, the Zn particles are all in mutual contact as well as in electrical contact with the steel substrate. The CPVC values in Zn-rich coatings range from 40 to 60%. There is some evidence that the electrical connectivity of the Zn particles carries over from the  $PVC = CPVC$  ( $\sim 60$ – $70\%$  by volume) to  $PVC = \text{volume percolation threshold}$ <sup>36</sup> for Zn ( $\sim 30\%$  by volume for spherical particles). Therefore, some sacrificial protection occurs over this range even while the Zn is being consumed by sacrificial oxidation. The percolation threshold for flake pigments may be different depending on particle alignment.<sup>37</sup>
4. The mode of protection is sacrificial as long as the Zn is electrically connected to the steel, as the Zn is more anodic (reactive) than Fe (major constituent of steel) in the electrochemical series. Then the

mixed Zn oxides formed in the sacrificial oxidation fill the damaged areas and also sometimes passivate the steel surface by their basic nature.

5. The organic or inorganic matrix of the coating must be stable under the basic conditions created by the zinc oxide, hydroxide, etc., formed from the oxidation of Zn in the presence of the electrolyte. It must also adhere well to the steel alloys and be stable in a corroding environment.
6. These primer coatings are usually top-coated to function optimally and have a long field lifetime. When used properly, these primers provide almost as much protection to steel as galvanizing. The coating system of a Zn-rich primer and an exterior durable topcoat provide both barrier and damage (sacrificial/cathodic) protection to steel substrates.

Much of what has been said concerning Zn-rich coatings holds true for Mg-rich coatings as well.<sup>29–31</sup>

Other metals and alloys have also been used as active metals in metal-rich coatings. Mn in particulate form has been used in coatings as an active metal pigment in the protection of steel<sup>38</sup>; various blends of Al pigments and Zn pigments have been proved to give corrosion protection to various steel alloys.<sup>39</sup> In summary, if one can get a stable metal  $M_1$  pigment – organic (or inorganic) matrix dispersion formed, and cast a film that will adhere to a less active metal  $M_2$  substrate such that there is electrical connectivity between the  $M_1$  particles and the  $M_2$  substrate, this substrate is now cathodically protected. For practical protection, the mixed potential developed at the  $M_2$  substrate surface,  $E_{M_1/M_2}$ , should be 100 mV below the  $M_1$  open circuit potential (OCP).

#### 4.11.2.3 Inhibitor Release Coatings

Like the cathodic protective coatings described, inhibitor release coatings that provide corrosion protection are active coatings, not just a passive barrier. In this class of coatings, the physical activity of dissolution and the physicochemical activity of substrate inhibition give protection to the substrate. Inhibitors are always discussed in books<sup>40,41</sup> and articles on corrosion control, but they are very far from being understood. Inhibitor release coatings are almost always designed and pigmented in an empirical manner with inhibitor release rates and time of release sustenance most often chosen by trial-and-error experimentation rather than by rational design. A paper by del Amo *et al.* is an example of this type of formulation methodology.<sup>42</sup> Sinko<sup>43</sup> gives an

interesting description of how important the solubility properties and other nonelectrochemical properties of inhibitive chromate pigments are to their successful use in coatings, and the challenges faced by those seeking to replace them for environmental reasons. Kendig and Buchheit also review chromates as inhibitors for Al alloy protection in coatings and give some very useful observations on the requirements for inhibitor pigments and the problems in controlling the 'controlled release' of inhibitors from coatings.<sup>44</sup> There are a considerable number of recent publications discussing new corrosion inhibitors and inhibitive pigments, but very little is said about their release rates in a lifetime of effective corrosion inhibition.

Water or aqueous electrolyte solutions, are the primary solvents that cause release of inhibitors from coatings. Therefore, the barrier properties of the coating toward water are important in inhibitor release. Very few studies have been published on the modeling of inhibitor release and the effects of solubility, water, geometry of coating, damage to coating, etc.<sup>45,46</sup> In general, organic inhibitors are more soluble and tend to leach out of the coatings much more rapidly than inorganic inhibitors. Many of the inorganic inhibitors used are so slightly soluble that they are classified as pigments. As is the case in most issues of coating design, the coating matrix polymer also helps to determine the release rate of inhibitors. The inhibitor release from a primer is minimized by the barrier properties of the topcoat in areas of no physical damage or defects. It appears that in undamaged coating systems, the small amounts of inhibitor dissolved near the primer coating–substrate interface may play a role in keeping any corrosion that occurs under the coating general and uniform at a low rate. Most inhibitors are controlled release materials in that they are only dissolved and become mobile in the presence of water, but many materials dissolve and disappear at a rate much faster than is necessary for corrosion inhibition, and hence have short lifetimes in coatings. An example of this is molybdate pigments, compared to chromate pigments. Even though the former may give inhibition, their solubility is great enough to leach out so rapidly that they cannot be considered true substitutes for chromates.

#### **4.11.2.4 Comments on 'Smart Coatings' and their Relative 'Intelligence'**

Much has been written lately about 'smart coatings,' and 'smart corrosion inhibitors'.<sup>47,48</sup> It is clear that most

of the authors seek to describe any coating or pigment from which the process of release is not 'dumb.' (Dumb apparently means that it dissolves in an uncontrolled manner whenever water is present.) They are trying to describe a coating system in which the release or chemical reaction within the coating that provides protection to the metal substrate occurs only in response to some external stimuli. Dramatic claims for release in the presence of threat from 'physical damage' or chloride ion concentration provide arguments for new designs of pigments or encapsulated inhibitors. This author insists on great care in accepting many of these arguments in differentiating one material from another. None of the writings in this field shows any numerical modeling or analysis of inhibitor release and substrate passivation and lifetime prediction, but only describes release testing into bulk solutions or trial-and-error formulated coating testing. This area of research has only been active for about 5 years (see, for example, Provder and Baghdachi,<sup>49</sup> and the coatings market place is very slow to accept new ideas or materials, so it is unlikely that many of these 'smart' coatings will appear in common use soon.

### **4.11.3 Components of Organic Coatings for Corrosion Control**

As described in [Section 4.11.1.1](#), the four basic component classes of a coating are polymeric binders, pigments, solvents, and additives. The polymeric binder matrix of a coating is the continuous phase of a well formed coating, which often provides a major part of the barrier protection provided by the coating. A brief survey of the most commonly used polymer classes for corrosion protective coatings follows. For further details on the properties of such polymers and their use, one needs to examine the general textbooks on coatings.<sup>16,50,51</sup> The focus in the following discussion is on the properties and uses of coating polymers unique to corrosion protection. The *Journal of Protective Coatings and Linings*, *Materials Performance* and the *Journal of Coatings Technology* often present articles on polymer suppliers and users and details of specific polymer use in corrosion protective coatings. In a general net or preapplication coating system, the solvent composition by volume ranges from 10 to 50% (zero in powder coatings), the polymer volume fraction ranges from 20 to 50%, the pigment volume concentrations range from 0 to 35%, and additives usually are at 15% or less.

### 4.11.3.1 Polymer(s) for Corrosion Control Coatings

In [Section 4.11.1.3](#), the desired attributes of a corrosion protective coating are given, and from these, the specific properties required of polymers for use in a corrosion-protective coating can be listed as follows:

1. Wet/dry adhesion – keeping the coating in contact with the substrate.
2. Low ion, water, and oxygen permeability – physical barrier effects.
3. Low conductivity – inhibit flow of current in local corrosion cells and stop ion and electron motion in film – electrical barrier effects.
4. Stability to its environment, stability to OH-driven basic hydrolysis and UV radiation, thermal stability, etc.
5. Strong adsorption of coating polymer to substrate interface – provides good wetting of substrate by coating system and reinforces the wet adhesion of the polymer mentioned in property 1.

These attributes are somewhat vague in qualitative definition and hard to define in numerical terms. All the properties described in the list can be altered by a detailed polymer composition as well as additives such as wetting agents. This must be taken into account when considering the information given on specific polymer classes as given in the following sections ([Table 1](#)).

#### 4.11.3.1.1 Epoxies

Perhaps the class of polymer type most commonly used in corrosion protective organic coatings is the epoxy class of polymers because of their good wetting of metal-metal oxide surfaces, excellent adhesion to most substrates, good to excellent chemical resistance, good dry electrical properties, relatively easily controlled crosslinking, wide range of commonly available molecular weights, relative ease of forming

pigment dispersions, wide range of crosslinking reactions available, and relatively good water resistance; epoxy type polymers can be modified to become a polymer engineer's dream. Epoxy polymers are very stable in the locally high pH ranges encountered due to oxygen reduction at metal substrates when corrosion occurs. Because of the good wetting and adhesion properties, epoxy-based coatings are more tolerant of poor substrate preparation than are many other polymer types. These polymers wet pigments and fibers well, and form stable composite films and structures with many pigments and fillers. A wide range of curing temperatures can be achieved, and by a suitable choice of the crosslinker, a wide range of polymer physical properties is available. Epoxies have a relatively strong tendency to pick up water due to humidity effects as well as in immersion, and they are plasticized by water.<sup>23,25</sup> Further, as a general class of polymers, epoxies tend to have poor UV resistance, because many epoxy precursors have phenyl groups in their structure. For this reason, many two-layer corrosion-protective coating systems use epoxy-based primers, while using a more UV-resistant polymer in the topcoat.

Epoxy materials can be designed to require heat curing as well as ambient curing. They have been applied in all types of commonly used equipment and can be used as solvent-borne systems, powder coatings, and waterborne, high-solid, and 100% solid variations. One specific class of epoxies that deserves special notice is the so-called fusion bonded epoxy (FBE) pipeline coatings class. Epoxy-polyamide polymers are often used in Zn-rich coatings because of their chemical resistance and adhesion to steel substrates. These coatings are high temperature cured epoxy powder coatings used for pipeline corrosion protection.<sup>52</sup> Further, qualitative comments specific to epoxy polymer use in corrosion protective coatings are given in several introductory texts discussing this class of polymeric materials.<sup>40,41</sup>

**Table 1**

Polymer	Property 1 wet adhesion	Property 2 chemical barrier	Property 3 electrical resistance	Property 4 exterior durability	Property 5 substrate wetting	Relative cost
Epoxies	+	+	+	+	+	Medium
Polyurethanes/polyureas	+	+	+	+	—	Medium to high
Acrylics	—	—	—	—	—	Medium
Alkyds	—	—	—	—	—	Low
Silicones	—	—O <sub>2</sub> /+H <sub>2</sub> O	—	+	—	Medium
Inorganic/sol-gels, etc.	—/+	—	—	+	+	Medium to high
Vinyls	—	+	+	—	—	Low

#### **4.11.3.1.2 Isocyanate-based polymers: polyurethanes and polyureas**

The second most commonly used class of polymers used for corrosion protection is isocyanate-based polymers, which includes polyurethanes of all types and the so-called polyurea coatings. Polyurethanes provide an excellent matrix for corrosion-protective coatings, but they are less tolerant as a class, being ill prepared substrates compared to epoxy coatings, with less wetting and adhesion properties. Aliphatic polyurethane (PUR) coatings are often used as topcoats in corrosion-protective systems because of their excellent UV resistance and barrier properties. Chemical resistance, abrasion resistance, and design flexibility are among the other strengths of coatings in this class of polymers. Aircraft coating systems,<sup>2</sup> chemical agent resistant coatings for military vehicles, and many other coating systems, including bridge coatings, have aliphatic PUR topcoats. Polyurethanes are based on reactions of monomeric or oligomeric isocyanates with polyhydroxyl oligomers<sup>53</sup> and vary in use from room temperature reactive curing to high temperature blocked isocyanate chemistry.<sup>54</sup> Most types of pigments, including active metal pigments such as Zn, have been used in PUR coatings. PUR-type coatings are sometimes difficult to use in primers as they are difficult to wet and adhere to as a substrate.

#### **4.11.3.1.3 Acrylics**

Acrylic polymers have been used in the coating industry for some time<sup>55</sup> and have great usefulness because of their UV stability and wide range of use. There are very many acrylic monomers so that copolymers of many types can be prepared using basic acrylic free radical polymerization. Similarly, very many side-groups of acrylic monomers are available, which allow crosslinking chemistries with many other polymer types.

#### **4.11.3.1.4 Alkyds**

Alkyds are among the longest used polymer classes in the modern coating era. They still have extensive use because of their relatively low costs and wide range of use. This class of polymers is, however, sensitive to basic hydrolysis, so use of unmodified alkyd polymers in purely corrosion-protective systems is definitely on the decline.

#### **4.11.3.1.5 Vinyl polymers**

Vinyl polymers is a name often used to identify polymers based on the vinyl group,  $\text{NCH}=\text{CH}_2$ ,

but really has been used to identify polymers and copolymers of vinyl chloride.<sup>3,16,40,41</sup> These polymers have been used extensively in the past for corrosion protective systems, but they often need large amounts of strong solvents to be applied properly, and thus their use has been heavily curtailed by VOC regulations for coatings. They also as a class have poor outdoor durability in UV exposure. They do, however, have excellent barrier properties, especially water resistance, and they are still used in some situations. They are often used as thick films applied in multiple layers. Chlorinated rubbers are often considered in this class of polymers.

#### **4.11.3.1.6 Mixtures including silicones**

Many of the polymer matrix systems for corrosion-protective coating systems are mixtures of more than one type of polymer. A full discussion of all the types of polymer chemistries available, is beyond the scope of this chapter, but is available in reviews and textbooks.<sup>41,50</sup>

#### **4.11.3.1.7 Sol-gel and hybrids**

Some coating matrix systems use ceramic-like chemistries for film formation, and have found use in corrosion-protective coatings, especially in Zn-rich primers (see Chapter 10 of Smith<sup>41</sup>). There is a current review on how these systems can handle a broad range of coating problems.<sup>56</sup>

### **4.11.3.2 Pigments**

Pigments are the second group of materials from which coatings are designed/formulated. As the heterogeneous phase in what might best be called a random two-phase particulate composite, pigments perform appearance functions and help provide protective functions. As discussed earlier, pigments help coatings provide corrosion protection by cathodic protection, barrier protection, and inhibitor release protection. In addition, colored pigments are used in corrosion-protective coatings for appearance purposes or to provide visual feedback to applicators about proper film thickness/opacity coverage.

#### **4.11.3.2.1 Inhibitive pigments**

Inhibitive pigments are perhaps the largest class of pigments used in corrosion-protective organic coatings. They include partially soluble inorganic compounds such as chromates, which are used in aircraft primers<sup>43,57</sup> and phosphates<sup>58</sup> as well as other related materials such as molybdates.<sup>59</sup> Other materials of this type are organic inhibitive pigments, controlled

release pigments<sup>60</sup> (the inhibitor is given off by the pigment in a controlled release manner), and ion exchange pigments.<sup>61</sup> These materials dissolve or release materials at a slow rate in the presence of water, and are thus present in high concentrations near a damaged site in a coating in exterior exposure. The release of materials from such pigments has been studied by several authors and found to be related to the efficiency of the pigment/coating polymer system.<sup>43,62</sup> The commercial literature of this area of materials is full of a lot of claims, and the formulator of coatings using such pigments is cautioned to carefully study coatings based on inhibitive pigments in tests that reflect the proper use conditions. In the case of chromate-replacement pigments, especially, matching release rates and inhibitive performance with no-chromate materials is very difficult indeed, and claims of replacement pigment manufacturers should be examined very carefully.

#### **4.11.3.2.2 Reactive metal pigments: spherical, lamellar, and platelet/flake**

The next class of pigments important in the formulation of corrosion-protective coatings are the reactive metal pigments used in formulating metal-rich, cathodic protective coatings. As discussed in [Section 4.11.2.2](#), metal-rich coatings are formulated with active metal pigments that are more reactive than the metal substrate the coating protects. Zn-rich coatings used for steel were the first such coatings of this type, and much of the literature on pigments for metal-rich coatings perforce concerns Zn pigments. However, this class of materials is expanding, and now includes Al,<sup>39</sup> Mg,<sup>29,30</sup> and Mn<sup>38</sup> pigments. A recent publication has even described the use of nano-Ti particles in corrosion-protective coatings, but gives no claims of cathodic protection.<sup>63</sup>

The important properties of metal pigments for use in coatings are as follows:

1. Particle size;
2. Particle size distribution;
3. Particle shape;
4. Surface oxide layer thickness or pretreatment.

The reactivity of metal particles is determined by their size (surface-to-volume ratio, specifically), increasing ( $3/\text{radius}$ ) for spherical particles. The shape of the particles, flakelike, needlelike, or spherical, affects their connectivity and thus their connectivity and percolation threshold.<sup>36,37</sup> Because of the importance of connectivity, metal-rich primer coatings are formulated near the CPVC, and thus particle

size, size distribution, and particle packing efficiency in such coatings are very important formulating issues that must be considered in the design of such coatings.<sup>1,3,27</sup> Their shape is also important for connectivity and percolation threshold determination, and the advantages of flakelike Zn pigments compared to an equivalent volume of spherical Zn pigments have been claimed.<sup>37</sup>

#### **4.11.3.2.3 Inert/extenders pigments**

The other class of coatings important for their use in corrosion-protective coatings is the inert/extender pigments. These pigments are used to control the PVC-related properties of coatings such as the dielectric, transport, and mechanical properties. They also tend to be lower in cost than other pigments, which helps explain their extensive use. Their function in coatings has been extensively discussed elsewhere,<sup>1,3,5,51</sup> and will not be discussed here. However, a subclass of extender pigments that is extensively used in corrosion-protective coatings is inertflake pigments such as Al, mica, exfoliated clays, and related materials. Because such pigments often align parallel to the substrate during coating film formation, they decrease transport in such films more effectively on a volume basis than spherically shaped pigments. Thus, if one wishes to increase the barrier properties by a given volume of extender pigments, those in a flakelike form are the most efficient if they align parallel to the substrate.<sup>62</sup>

#### **4.11.3.2.4 Colored pigments**

Colored pigments are used in corrosion-protective films to help provide a more pleasing appearance to such coatings and the substrates they protect. The use of colored pigments also helps provide a visual guide to hand-applied coatings. The major issues requiring consideration in colored pigments in corrosion-protective coatings is whether the coatings will be used on the exterior or the interior. For the former, pigments should be UV stable and not cause photo-oxidation, as do untreated TiO<sub>2</sub> pigments. Most often, inexpensive colorants such as iron oxide red, carbon black, or yellow iron oxide are used in corrosion protection systems because of their stability.

#### **4.11.3.3 Additives: Surfactants, Rheological Control Agents, Flow Agents, Defoamers, Wetting Agents, Dispersants, etc.**

The term additives is a general term used for describing those materials that are added in small amounts,

usually less than 1% by weight, to coatings to control the properties of the liquid coating before and during application. Included in this class of materials for coating formulation and design are surface active materials, such as wetting agents, pigment dispersants and defoamers, biocides, and materials for rheological control of the liquid coatings. Coalescents and plasticizers, which affect the short-term behavior of polymers during film formation, are also included in this class of materials. Some additives are used to control and improve the properties of the solid film, and these include UV absorbers, light stabilizers, mildew retardants, and fire retardants.<sup>36,37</sup>

#### 4.11.3.4 Solvents/Carrier Fluids

Solvents and dispersion carrier fluids (i.e., water in latex-based paints) play a key role in coatings, as they are liquids that enable the coating to be in liquid form for proper coating application. For cost, environmental, and legal reasons, the minimum amount of solvent is used in formulating a coating, and the type of solvents one can use in coatings is subject to severe restrictions. The legislation in this area is continually changing, and the formulator is advised to check on the specific regulations on solvent use that apply to the location of his coatings.

For corrosion-protective coatings, a primary consideration is, whether the solvent remains in the coating long enough for the coating to complete film formation, and then leaves the coating and does not interfere with the full development of coating properties. For example, if the formulator uses a solvent that does not completely leave the film during film formation, the residual solvent can act as a plasticizer and lower the effective  $T_g$  of the coatings, which will reduce the coating barrier properties. If the solvent leaves the film before polymer crosslinking is complete, the film formation process will remain incomplete, and the full development of coating properties will not occur. Again, the formulator is referred to monographs on coatings for further guidance on solvent choice and usage.<sup>51</sup>

#### 4.11.3.5 Catalysts for Reactive Polymer (Usually Two Component) Curing

Catalysts to accelerate the curing of coating polymers are also an important type of additive.<sup>50,58</sup> Many of the polymers used in corrosion protective coatings are two-component systems that use reactive cure as the mode of film formation. These curing systems

often require catalysts to crosslink and undergo film formation properly.<sup>16,17,52–54</sup> Epoxy-based coatings require catalysis in their use, and detailed information on individual coating polymers is most often available from the polymer manufacturer. Similarly, catalysts are commonly used in polyurethane/polyurea coatings, but recommendations from the manufacturer of the polymer under consideration are probably the best starting point for formulation practice in PUR systems.

#### 4.11.4 Coatings Application Methods and Corrosion Protection

Since corrosion in coated metal substrates is a problem that begins locally and then may grow into a global concern, the elimination of all coating defects during the coating application process is of great concern. For this reason, the method by which a corrosion-protective coating is applied to the metal substrate is extremely important for the successful use of such a coating. Also very important to the proper performance of a corrosion-protective coating is the proper preparation of the metal surface to receive the coating. For example, an improperly applied spray coating will make a coating-metal substrate system liable to corrosion. For this reason, corrosion-protective coatings that are field applied are inspected after application to ensure that no defects are present before a coating system is allowed to go into field use. The Society for Protective Coatings (SSPC, see [www.sspc.org](http://www.sspc.org)) has several manuals for coating inspection and the National Association of Corrosion Engineers, Intl (NACE, see [www.nace.org](http://www.nace.org)) has an extensive set of training programs for training personnel as coating inspectors.

A corrosion-protective coating correctly applied to a well prepared metal substrate is crucial for achieving the proper performance from the coating substrate system. This is especially crucial for systems in situations where field repair of coating imperfections is not achievable, such as buried pipelines or off-shore oil platforms. Because of this, proper coating application is paramount for corrosion-protective coatings. Much of the high-quality corrosion protection inherent in recent automobiles is due to the use of cathodic electrodeposition primers used over Zn/Zn-alloy galvanized steel.

A more detailed discussion of the application methods and procedures of corrosion-protective organic coatings is given in this volume, and this

subject receives no further discussion here. For further reading in this area, see the references listed under Further Reading.

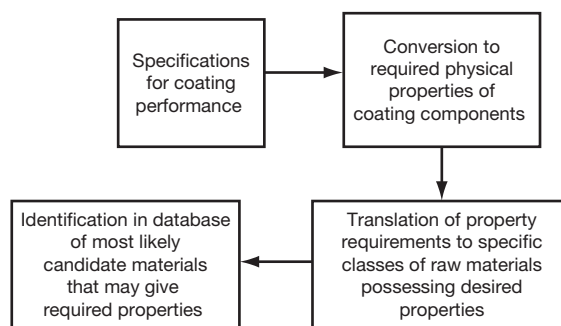

#### 4.11.5 Coating Wetting and Adhesion in Coatings

General wisdom has it that adhesion, especially ‘wet adhesion,’ is a key attribute for corrosion-protective coatings.<sup>7</sup> To function properly, a coating must wet and adhere to the metal substrate it is being used to protect.<sup>1,11</sup> Many adhesion problems in actual use are solved by properly preparing the surface of the substrate for the coating application process. Additives for improved wetting are often used in corrosion-protective coatings. Because of their high surface energies, the ideal surfaces for wetting have been considered to be clean metals or metal oxides. Such surfaces, along with coatings that strongly wet them, such as epoxy-polyamide-based coatings over pretreated steel, have given excellent adhesion of the coatings and thus good corrosion protection. However, recent developments in science have been giving the hope of achieving improved adhesion by true covalent bonding across the coating-substrate interface. There are many claims for such pretreatments/coatings, which achieve covalent bonding directly across the coating-substrate interface. Many of these claims are based on the use of functional silanes and their metallic analogs. The surface density of such covalent bonds is still highly variable, and no good tests are available to measure the extent of covalent bonding across an interface in the coating-metal substrate situation. Most of the difficulties in this area lies with issues of measurement of ‘adhesion’ several recent articles<sup>65,66</sup> indicate that there measurements in ‘adhesion’ have improved and that further improvements in this area may be expected soon.<sup>67,68</sup>

#### 4.11.6 Coatings Formulation/Design

##### 4.11.6.1 Principle Objectives of Formulation – Coatings Design

For many systems, the coating design process can be summarized as shown in Figure 5. One first determines the desired properties (specifications) of the coating, translates these to the physical properties required of the coatings, and then attempts to convert these requirements to material choices for the composite, that is, the coating. Converting materials

**Figure 5** Idealized case of raw material selection.

specifications to materials choice is one of the most difficult steps in the design process.<sup>15</sup> Additionally, it should also be noted that the ‘best’ coating for any situation is likely going to be a balance between minimizing cost while achieving – within tolerances – the performance requirements.

While working on coating design, work at North Dakota State University (NDSU) has been performed to accomplish the following:

- Put coating design on the same strong technical basis as any other type of engineering design;
- Identify the logic of paint formulation;
- Emulate as much as possible the practice of paint formulation development;
- Determine steps in setting coating specifications – performance property requirements – and converting them into a set of raw material identities, concentrations, and rules for coating manufacture (order of addition, etc.) and application to a substrate;
- Develop basis for coating design system to assist coating formulators;
- Software development for formulator support.

One can think of each of the processes shown in Figure 5 as an operation on a set of databases of material information, specification information, and coating application information. From this alternative viewpoint, the process of formulation would schematically appear as shown in Figure 6. (At the bottom of Figure 6, the  $F$  is used to represent formula.) One might think of each step in choosing materials and processes and applying specifications, as applying a mathematical filter to a database of choices yielding reduced databases, from which the formulator/designer makes his final choices. This type of analysis of the formulation process seeks to reduce the often intuitive reasoning that is common in many paint laboratories to a more scientific process analogous to the design process used in many scientific disciplines.<sup>69,70</sup>

Another description of the coating 'formulation' or design process is given in **Figure 7**, in which the consideration of legal/environmental restrictions, curing restrictions due to the site or substrate, and the requirements of individual coating classes are also considered. Other constraints faced by the formulator/designer are production equipment capacity for producing paints of various classes, application equipment available to the user, and substrate size, solvent and temperature sensitivity, corrosion sensitivity, and surface preparation.

There are various ways to organize a database for formulation, and in the following section, several

schemes that fit in with the logic of **Figures 6 and 7** are presented.<sup>14</sup> **Figure 8** shows a raw material (RM) database structure compatible with these operational methods of formulation. **Figure 9** gives an alternative RM data base focusing on polymer/binder classes for coatings as well as coatings classes.

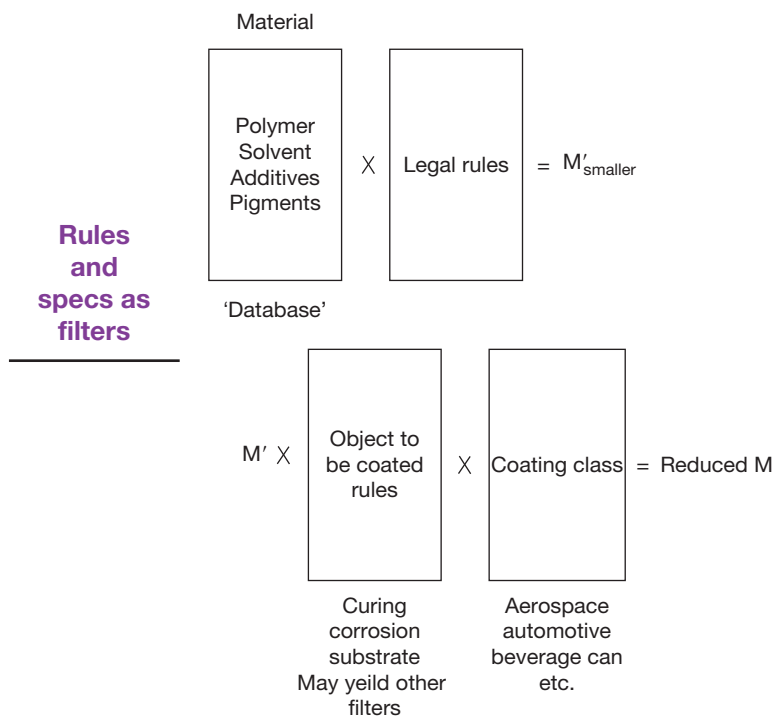

If the RM databases are cast in the proper format, one can use the formulation/design logic discussed earlier, shown in a more detailed form in **Figure 10**.

If one wishes to consider previous formulations/designs to reduce the amount of decision making that needs to be performed in these processes, one can use the flow process shown in **Figure 11**. Once an original candidate coating design/formulation is available, the development and testing protocol found in **Figure 12** can be used.

These processes can be quite slow when run in the sequential, serial form as shown in **Figure 12**. There are also several problems in trying to reduce the formulation process to a computer-driven procedure. Among these are difficulties in the correlation of coating specifications with design rules developed for translating RM properties to RM choice, the need to narrow the range of raw material availability, or conversely, database limitations due to RM availability. Raw material variability from single or multiple sources is another problem that must be

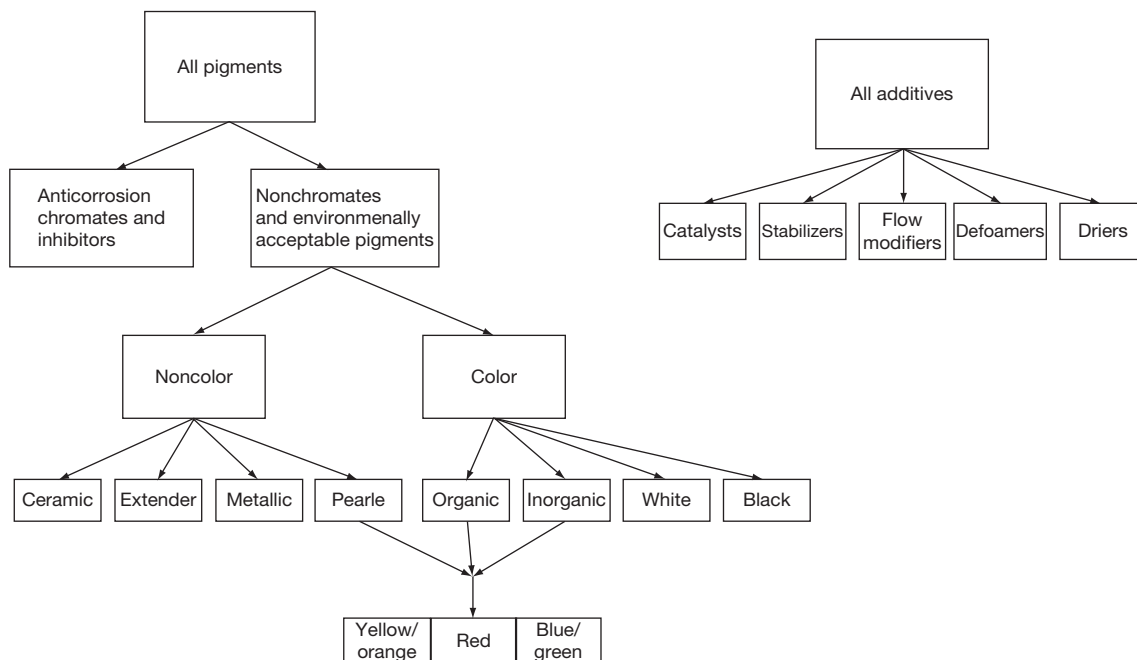

**Figure 6** Schematic of formulation logic – alternative view.

**Figure 7** Alternate schematic of materials choice in coating design/formulation.

### Pigment and additive raw material classes

**Figure 8** Schematic of possible coatings raw material database organization.

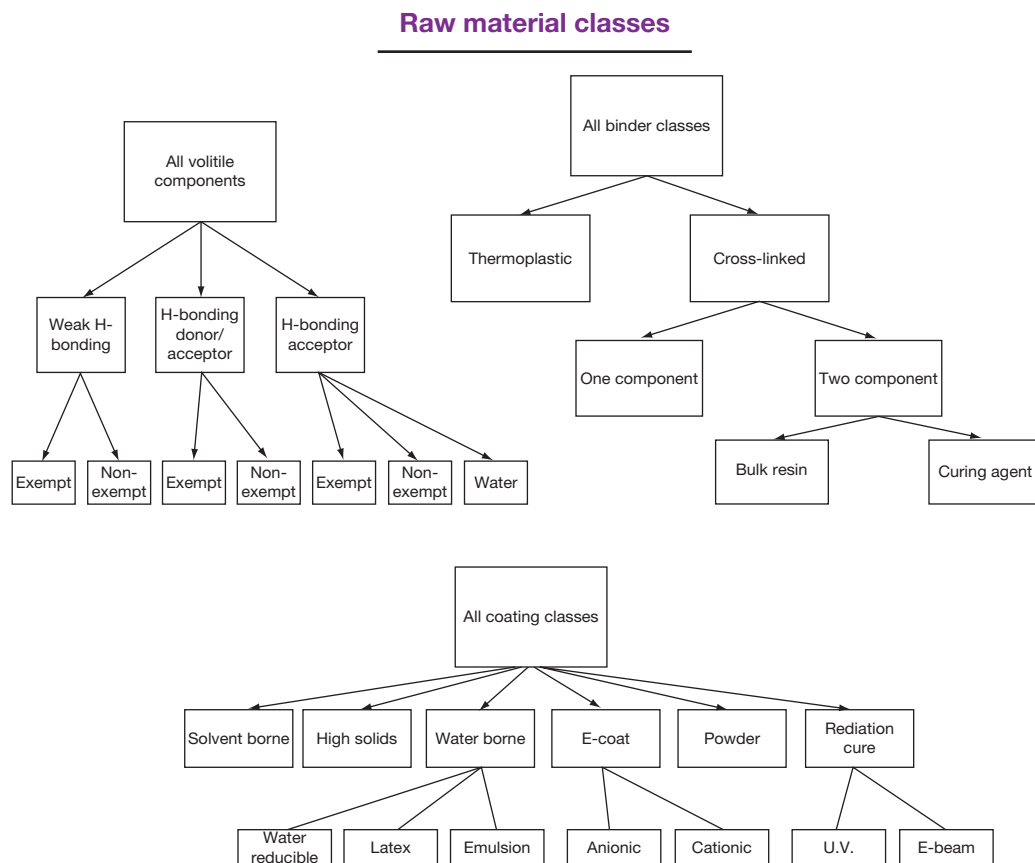

considered, and procedures included in the formulation process to examine the final properties and quality of the coating for sensitivity to RM variability.

#### 4.11.6.2 Volume Effects in Coatings

As mentioned earlier, and reiterated in a recent publication,<sup>1</sup> volume effects are extremely important in pigmented organic coatings, as the volume concentration of materials is the relevant concentration parameter for many of the physical properties of coatings. This is especially true for pigments and the term PVC is commonly used in coating studies. Because of system requirements, it is often considered fruitful to formulate at fairly high PVC levels. Although the specifics differ for every coating system, in general the most expensive component of the system is the pigment or colorant. This is followed by the binder system. The least expensive materials are the solvent (which is not present in the dry film) and the filler or extender pigment. This has made knowledge of the CPVC an important formulating variable, and crucial to coating design and the understanding of corrosion-protective coatings.<sup>71</sup> The CPVC measures the highest volume fraction of solid pigment that can

be packed into a coating without introducing air voids. The parameter  $A$  ( $\equiv$  PVC/CPVC, the reduced pigment volume concentration) is often used in interpreting and predicting coating behavior. Coating properties that are directly affected by  $A$  are given in [Table 2](#). The use of  $A$  in coatings design is discussed extensively in Bierwagen,<sup>1,6,7</sup> Bierwagen *et al.*,<sup>3</sup> Hare,<sup>27</sup> and Nanna and Bierwagen.<sup>29</sup> Theoretical studies of nonuniformities in particle packing and their impact on CPVCs in ‘real’ coating systems have given further insight into PVC issues in coatings.<sup>72,73</sup> The knowledge of coating performance as a function of  $A$  is often utilized in coating design once the pigments to be used in the coating are identified. As discussed in [Section 4.11.3.2.2](#), this is especially critical in metal-rich coatings.

Numerical guidelines for  $A$  levels for formulation of corrosion-protective coatings have focused on the effects of the CPVC on coating performance characteristics. Some figures describing the qualitative variation of coating properties with PVC or  $A$ , pertinent to corrosion protection are given in the following section. [Figure 13](#) (taken and modified from Bierwagen *et al.*)<sup>3</sup> shows the relation between pigment and polymer components, including the adsorbed layer on the pigment and void fraction above the CPVC, that occur

**Figure 9** Alternate coating raw material database organization.

in the coating as a random two-phase (below the CPVC) and three phase (above the CPVC) composite. **Figure 14** shows schematically the increase in permeability that occurs in a coating above the CPVC, while **Figure 15** shows the sudden drop in film resistance measured by the low-frequency impedance modulus  $|Z_0|$  or noise resistance,  $R_n$ , that occurs at the CPVC. Similarly, the film capacitance measured in an aqueous electrolyte will increase drastically above the CPVC because of water intrusion into voids and corrosion resistance, measured in accelerated testing salt spray, will increase drastically above the CPVC.<sup>71</sup> Thus, a coating formulated above the CPVC provides hardly any barrier protection and often gives poor adhesion in certain types of polymers. Primers can be formulated above the CPVC, if they are coated with a topcoat formulated below the CPVC. This gives a total coating system that does not have a porous structure open to water/electrolyte intrusion. This is often done with Zn-rich primers that are formulated near the CPVC.

The barrier properties of coating are ideally maximized at the CPVC, but in practice, it is known that voids sometimes appear in real coating systems

below the CPVC.<sup>1</sup> These voids form in local areas of the coating where the local PVC exceeds the CPVC because of the nonuniform distribution of pigment and polymer throughout the coating film. This can be described by a parameter named coarseness (from Torquato),<sup>4</sup> used to analyze these results properly. It helps to interpret correctly what happens in films as the PVC approaches the CPVC.<sup>74,75</sup> A schematic of these effects, taken from calculations described in earlier work from this lab, is shown in **Figure 16**.

The interpretation of these data were based on an analysis of coatings as a random composite in which the local PVCs could vary from the calculated (global average) PVC as measured by the coarseness of the system. These variations could occur in coatings due to poor manufacture, film formation or application problems, or other processes in the coating that tend to separate the pigments from the polymer, such as flocculation in storage. Incorporating the coarseness parameter in the analysis, enables one to numerically predict the effect of poor, nonuniform distribution of particulate materials in a coating. The analysis also showed how such coarseness could affect many of the

**Figure 10** Raw materials choice flow process for coating design.

properties of coating films, especially those related to corrosion protection. These results helped to interpret the empirical observation that most corrosion-protective primer formulae, dependent on barrier effects as part of their protective properties, had  $\lambda$  values of  $\sim 0.85$ . One would actually expect that these coatings would be formulated at  $\lambda \approx 1$  for maximum barrier protection, because one would assume that it would be the best value for corrosion protection. However, if one analyzes the onset of voids as a function of coarseness, one rapidly determines that there is a very small but finite probability for voids occurring above  $\lambda = 0.85$ , but below this PVC value, the probability is very small. The margin of tolerance formulating at  $\lambda$  values of  $\sim 0.85$  given to the designer of primer barrier coatings is crucial for avoiding completely the onset of voids in the coating film.

There are no efficient experimental methods other than the manual interpretation of SEM cross-sections to estimate coarseness. A proper microview of the coating system is necessary to properly analyze the manifestations of coarseness throughout a film. We have been trying to use SEM photomicrographs for estimating coarseness, but a detailed three-dimensional characterization of pigment particle distribution in a paint film is necessary for an accurate estimate of coarseness.

#### 4.11.6.3 Setting Formulation Goals

A coating is chosen for purchase, or designed/formulated, based on the requirements of the customer or as translated by sales/marketing and given to technical/research personnel. For example, corrosion-protective coatings often have a lifetime of performance measured by a specific accelerated test method in a specific set of conditions. An idealized list of specified properties for an organic coating is given in [Table 3](#). These specifications could be considered in a design process, as shown in [Figure 7](#).

The specifications for a coating are usually determined by the following:

1. Exposure environment(s) of use;
2. Properties of substrate – asset to be protected
  - a. general chemical and mechanical properties of bulk substrate and its surface
  - b. pretreatment of the substrate and resultant surface properties;
3. Desired lifetime of use.

The specifications can often be converted into the required properties of coating under the following classifications:

**Figure 11** Flow process for coatings formulation with former formula for use as precedent and guide.

1. Diffusion and transport;
2. Thermal and mechanical;
3. Electrical;
4. Optical and color;
5. Chemical resistance;
6. Acid/base resistance;
7. UV resistance;
8. Degree of crosslinking;
9. Solvent and water resistance.

### Development rules

**Figure 12** Development, testing, and pilot scale production flow process once an initial formula is proposed.

As described earlier, these requirements are converted into material properties, and material selections are made based on availability, material cost, and cost restrictions of the customer, subject to legal, toxicity, and ecological restrictions.

#### 4.11.6.3.1 Use of combinatorial methods in coating design and choice

The new combinatorial methodologies developed for the pharmaceutical and electronics industries are now being applied to improving coatings.<sup>76,77</sup> These

**Table 2** Paint properties affected by  $\Lambda$ , the reduced pigment volume concentration (PVC/CPVC)

Gloss	Blistering
Flexibility (elongation)	Enamel holdout
Tensile strength	Penetration control over porous
Color development (tint acceptance)	Density (specific volume)
Hiding – contrast ratio	Durability
Block resistance	Electrical resistance
Permeability	Cold crack resistance
Wet abrasion (scrubbability)	Dielectric constant
Stain removal	Adhesion
Corrosion resistance (salt spray resistance)	Dispersion

**Figure 13** Coating film component variations with PVC.**Figure 14** Organic coating film permeability.**Figure 15** Film resistance as  $R_n$  or  $|Z_0|$  or vs. PVC.**Figure 16** Film component volume relations with coarseness effects for CPVC = 0.66.

methods speed up considerably the time-consuming conversion of material requirements to material choice in the design of coatings and related materials. Combinatorial methods convert one-at-a-time serial methods of sample preparation and testing into parallel methods that, in the case of coating testing, convert single sample testing to 24-samples-at-a-time high-speed testing. For example, these methods have been used in a crude form to modify an automotive coating to one suitable for the corrosion protection of bronze statuary.<sup>78</sup> More recent developments have focused on the development of high throughput screening methods for testing<sup>79,80</sup> and designing corrosion-protective coatings.<sup>81</sup> Coupled with the database-driven material choice methods described earlier, the numerical methods available for polymer and pigment choice, combinatorial coating design, and testing will greatly accelerate the design and testing cycle for corrosion-protective organic coatings.

**Table 3** Simplified coating specification list for coatings design

---

Issues determining coatings design/formulation coatings systems specifications/performance requirements
Cost
Number of layers (more than one layer $\equiv$ system)
Topcoat properties – usually contain color and optical properties plus the barrier and chemical and UV resistance properties
Primer properties (usually contains corrosion resistance properties)
System physical properties including color and mechanical properties
System chemical resistance properties
System exposure resistance properties
Application method and flow properties

---

#### 4.11.7 Coatings Design and Testing: Choosing the Final Formula

The final stages of coating design involve the examination of experimental formulations according to tests that have been chosen to determine whether the coating films resulting from a proper application of the prototype formulations meet the specifications for the new coating system. The type of tests performed often is discussed in the literature,<sup>2,17,82</sup> but no one set of specifications is agreed upon by all users. There have been many arguments about the validity of test methods to evaluate protective coating systems, including disagreements on whether cyclic or continuous exposure tests are more accurate and predictive. Many of these issues have been discussed in previous reports of this laboratory.<sup>83</sup>

The testing of corrosion protection is discussed in detail in earlier volumes of this series and will not be discussed in detail here. The steps in coating development are

1. Developing the prototype formula;
2. Converting formulation specifications to qualification tests;
3. Short-term lab testing;
4. High-throughput combinatorial testing;
5. Modifying the prototype formula;
6. Accelerated testing/lifetime prediction.

One can see how these steps fit in the schematic of **Figure 12** on coating development and testing. As shown in **Figure 12**, no information from testing should ever be discarded or unrecorded.

As mentioned earlier, this laboratory has been working on metal-rich primer coatings for corrosion protection. A brief discussion of the testing involved in the Zn-rich subclass of such coatings will illustrate the type of corrosion-related testing done. There has been some recent work on lifetime of protection of Zn-rich primers,<sup>84,85</sup> but little has been done on characterizing quantitatively their performance or their lifetime of corrosion protection. Unfortunately, the science and technology of Zn-rich primers is assumed to be a ‘mature’ technology, to which little technical improvement can be made. This is definitely not true, as clearly indicated by the recent work of Marchebois *et al.*,<sup>86</sup> and Böhm and co-workers.<sup>36</sup> There is a need to re-examine Zn-rich coatings over steel substrates by the experimental and theoretical methods that we have developed for the examination of Mg-rich coatings over Al alloys.

The characterization tools previously used on metal-rich coatings for the active protection of metal substrates are as follows:

Open Circuit Potential (OCP)( $E_{\text{corr}}$ ) measurements versus exposure time to verify electrochemical cathodic protection;  
 Electrochemical Impedance Spectroscopy;  
 Electrochemical Noise Studies;  
 Weight Gain/loss;  
 Optical Microscopy and local XRD;  
 SEM, EDX, some local XPS for Zn reaction product ID.<sup>32,33,37,84–86</sup>

Little that is new in characterization methodology has been introduced for this class of coatings in recent years, and subsequently, little that is new in coating technology or product protection performance for this class of coatings has entered the marketplace recently. Specifically, very little data acquisition and analysis, focused on improving costing system performance or lifetime, has been described in the recent literature. Further, little has been done to acquire proper time series data for lifetime/durability prediction. There has been no true detailed modeling of Zn-rich coatings as a material system to assist material design based on advanced characterization. Surprisingly, in the face of their successful use in many areas of electrochemical science, there has been no inclusion of new local measurement techniques, especially scanning probe methods for the characterization and modeling of Zn-rich coating performance. No analyses of cyclic transport and no electrochemical data from drying cycles have been made as aqueous electrolyte required for data acquisition.

### 4.11.8 Summary and Conclusions

The design/formulation of a corrosion-protective organic coating is a very challenging design procedure, often involving 20–40 individual materials that must be properly chosen, mixed, packaged, and applied as a final coating to a metal substrate. The design procedure is quite complex, as also the formulation of the proper choice of matrix polymer and pigments of the corrosion-protective coating system. The basic information on such choices has been given, and the process of choosing raw materials has been described. A general bibliography on monographs and textbooks pertinent to corrosion-protective coating design is given.

### Glossary

**D conduction** The behavior of a paint film (or an area of a paint film) whose trends in conductivity follow directly the solution in which it is immersed.

**Donnan effect** Where species of a particular size or charge are unable to pass through a semipermeable membrane, an additional osmotic pressure is created across the membrane.

**I conduction** The behavior of a paint film (or an area of a paint film) whose conductivity follows inversely to the solution in which it is immersed.

**Ionogenic** Capable of forming ions; used especially of a molecule that can dissociate into fixed ions and mobile counterions

**Isoelectric (point)** The pH at which a particular molecule or surface carries no net electrical charge.

**Zwitterion** A chemical compound that is electrically neutral but carries formal positive and negative charges on different atoms.

### Abbreviations

**AC** Alternating current

**DC** Direct current

**PVC** Pigment volume concentration

**RH** Relative humidity

### 4.12.1 Introduction

From time to time, astronomical estimates are made of the annual destruction of metals, particularly iron and steel, by corrosion. Paint is one of the oldest methods used for delaying this process. However,

it is somewhat surprising that its protective action has only recently been systematically examined.

Since iron is the commonest structural material, the following discussion will be limited to the behavior of this metal. The general principles can readily be extended to nonferrous metals.

#### 4.12.2 The Corrosion of Iron and Steel

Corrosion is essentially the conversion of iron into a hydrated form of iron oxide, that is, rust. The driving force of the reaction is the tendency of iron to combine with oxygen. It has long been known that iron is not visibly corroded in the absence of either water or oxygen. The overall reaction in their presence may be written as:

When the supply of oxygen is restricted, the corrosion product may contain ferrous ions. The overall reaction can be broken down into two reactions, one producing electrons and the other consuming them:

Or, combining these:

In the presence of oxygen, the ferrous hydroxide will be further converted into one of the forms of rust, for example,  $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ .

Ferrous hydroxide is soluble (9%) in pure water, but slight oxidation renders it appreciably less soluble. Thus, in the presence of water and oxygen alone, the corrosion product may be formed in close contact with the metal and attack will consequently be stifled. In the presence of an electrolyte such as sodium chloride, however, the anodic and cathodic reactions are modified, ferrous chloride being formed at the anode and sodium hydroxide at the cathode. These two compounds are highly soluble and not easily oxidized, so they diffuse away from the sites of formation and react at a distance from the metal surface to form ferrous hydroxide, or a basic salt, which then combines with oxygen to form rust with the regeneration of sodium chloride:

Consequently, rust is formed at a distance from the metal, and so stifling cannot occur.

It follows that when iron rusts, the conversion is accompanied by a flow of electrons in the metal from the anodic to the cathodic regions and by the movement of ions in solution. This conclusion has been firmly established by Evans<sup>1</sup> and his coworkers, who have shown that in the case of a number of metals under laboratory conditions, the spatial separation of the anodic and cathodic zones on the surface of the metal was so complete that the current flowing was equivalent to the corrosion rate. In order to inhibit corrosion, it is necessary to stop the flow of current. This can be achieved by suppressing either the cathodic or the anodic reaction, or by inserting a high resistance in the electrolytic path of the corrosion current. These three methods of suppression are called cathodic, anodic, and resistance inhibition, respectively.

The effect of paint films on the cathodic and anodic reactions will now be considered and the factors which influence the electrolytic resistance of paint films will be discussed.

#### 4.12.2.1 The Cathodic Reaction

The cathodic reaction in neutral solutions usually involves oxygen, water, and electrons:

If a paint film is to prevent this reaction, it must be impervious to electrons; otherwise, the cathodic reaction is merely transferred from the surface of the metal to the surface of the film. Organic polymer films do not contain free electrons, except in the special case of pigmentation with metallic pigments; consequently, it will be assumed that the conductivity of paint films is entirely ionic. In addition, the films must be impervious to either water or oxygen, so that they prevent either of them from reaching the surface of the metal.

The rate of corrosion of unpainted mild steel immersed in seawater, found by Hudson and Banfield,<sup>2</sup> was found to be  $0.089 \text{ mm year}^{-1}$ . Hudson<sup>3</sup> obtained a similar average value for steel exposed to the open air under industrial conditions ( $0.051 \text{ mm year}^{-1}$  at Motherwell and  $0.109 \text{ mm year}^{-1}$  at Sheffield). This rate of corrosion corresponds to the destruction of  $0.07 \text{ g cm}^{-2}$  of iron per year. Assuming that the corrosion product was  $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ , this rate of attack represents the consumption of  $0.011 \text{ g cm}^{-2}$  of water per year and  $0.03 \text{ g cm}^{-2}$  of oxygen per year.

**4.12.2.1.1 Diffusion of water**

The diffusion of water through paint films has been measured by various workers. The weight of water, which could diffuse through three clear vehicles and eight paint films, each 0.1-mm thick, at a relative humidity (RH) of 85–100%, has been calculated on the assumption that the water would be consumed as soon as it reached the metal surface, that is, the rate-controlling step was the rate of diffusion of water through the film, as shown in [Table 1](#).<sup>4,5</sup>

By means of an ingenious instrument, which measured the ‘wetness’ of a painted surface, Gay<sup>6</sup> found that although the relative humidity of the atmosphere varies appreciably, this is not reflected in the behavior of paint films. He found that under normal conditions, paint films are saturated with water for about half of their life, and for the remainder, the water content corresponded with an atmosphere of high humidity; furthermore, the relative humidity of sea water is about 98%. It follows from [Table 1](#) that the rate at which water passes through paint and

varnish films is many times greater than the water consumed by an unpainted specimen exposed under industrial conditions or immersed in the seawater.

**4.12.2.1.2 Diffusion of oxygen**

The diffusion of oxygen through polymer films has been examined by a number of workers. Guruviah<sup>5</sup> measured the permeability to oxygen of films cast from five paints ([Table 2](#)) and compared the results with the corrosion rates of painted steel panels, when exposed to salt spray and humidity for 1000 h. He concluded that “the low corrosion rate could be explained by the low permeability to oxygen of the films”; however, when his values for the permeability are plotted against the corrosion, it is clear that this conclusion is without foundation.

The mass of oxygen, which could diffuse through unit area of a 0.1-mm thick film under a pressure gradient of 2 kPa of oxygen, has been calculated, and is shown in [Table 2](#).<sup>5,7,8</sup> Baumann<sup>9</sup> has claimed that these figures are about 100 times too high, but

**Table 1** Diffusion of water through paint films of thickness 0.1 mm

<i>Vehicle</i>	<i>Pigment</i>	<i>Rate of water consumed (g cm<sup>-2</sup> year<sup>-1</sup>)</i>	<i>Reference</i>

Epoxy polyamide	Iron oxide, 35% PVC	0.002	5
Chlorinated rubber	Iron oxide, 35% PVC	0.006	5

Unpainted steel consumes oxygen at a rate of 0.020–0.030 g cm<sup>-2</sup> year<sup>-1</sup>.

this is because he compared the amount which could pass through in a day with that passing in a year. Haagen and Funke<sup>10</sup> concluded that the permeation of water was too great and that of ions too small to be the controlling factor and suggested that the rate controlling step was the rate of the diffusion of oxygen. However, if this were the case then painted steel upon exposure should corrode at a rate varying from that of unpainted steel to about a tenth of that value. Since painted steel upon exposure does not corrode immediately at this rate, it is concluded that the rate of the diffusion of oxygen is not the controlling factor.

The general conclusion drawn from these considerations is that paint films are so permeable to water and oxygen that they cannot inhibit corrosion by preventing water and oxygen from reaching the surface of the metal, that is to say they cannot inhibit the cathodic reaction.

#### 4.12.2.2 The Anodic Reaction

The anodic reaction consists of the passage of iron ions from the metallic lattice into solution, with the liberation of electrons, which are consumed at the cathode by reaction with water and oxygen. There are two ways in which the anodic reaction can be suppressed:

- (a) If the electrode potential of iron is made sufficiently negative, positively charged iron ions will not be able to leave the metallic lattice, that is, cathodic protection.
- (b) If the surface of the iron becomes covered with a film impervious to iron ions, then the passage of iron ions into solution will be prevented, that is, anodic passivation.

### 4.12.3 Mechanisms of Paint Protection

#### 4.12.3.1 Cathodic Protection

In order to make the potential of iron more negative, the iron must receive a continuous supply of electrons. As has already been pointed out, polymer films do not contain free electrons; there remains the possibility of obtaining these from a pigment. The only pigments which contain free electrons are metallic ones, and such pigments will protect iron cathodically if the following conditions are fulfilled:

- (a) The metallic pigment must be of a metal less noble than iron, otherwise the iron will supply

electrons to the pigment, which will be protected at the expense of iron.

- (b) The pigment particles must be in metallic, that is, electronic, contact with each other and with the coated iron; if they are not, the movement of electrons cannot occur.

It has been shown<sup>11</sup> that zinc dust is the only commercially available pigment which fulfils both conditions. Paints capable of protecting steel cathodically can be prepared with zinc dust, provided that the pigment content of the dried film is of the order of 95 wt%; both organic and inorganic binders have been used, the latter being very useful when resistance to oil or organic solvents is required.

These paints are quite porous and function satisfactorily only in the presence of an electrolyte – for example, water containing a trace of salt, or acid – which completes the circuit formed by the two metals. It might be thought that the useful life of these paints is limited to the life of the electronic contact between the zinc particles, but this is not correct. Under normal conditions of exposure, the electrons supplied by the zinc to the steel are consumed at the surface of the steel by reaction with water and oxygen (cathodic reaction), with the formation of hydroxyl ions. Consequently, the surface becomes coated with a deposit of the hydroxides, or carbonates of zinc, calcium, or magnesium, which blocks the pores in the film and renders it very compact, adherent, and impervious. Thus, although metallic contact between the steel and the zinc dust particles is essential in the early stages of exposure, the paints provide good protection after that contact has been lost. Paints containing less zinc dust have been known for a long time, but as the zinc dust concentration is decreased, protection at scratch lines or at gaps in the coating decreases; however, such paints frequently afford good general protection owing to the formation of deposits (consisting of oxides and carbonates) on the metal at the base of the coating.

Recently, it has been pointed out that manganese satisfies both conditions since the oxide film around the particles contains ions in two states of oxidation, and it has been claimed that cathodically protective paints can be prepared with this pigment.<sup>12</sup> Exposure trials in this country have indicated that at an inland site their behavior is comparable with the zinc dust controls, but that they were inferior to zinc-rich paints under severe marine conditions. It has been suggested that they might be of interest where zinc was unsuitable owing to toxicity.<sup>13</sup>

#### 4.12.3.2 Anodic Passivation

When a piece of iron is exposed to the air, it becomes covered with an oxide film. Upon immersion in water or solutions of certain electrolytes, the air-formed film breaks down and corrosion ensues. In order to prevent corrosion, the air-formed film must be reinforced with similar material, or a ferric compound, and there are two ways in which this may be achieved:

- (a) The pigment may be sufficiently basic to form soaps when ground in linseed oil; in the presence of water and oxygen these soaps may autoxidize to form soluble inhibitive degradation products.
- (b) The pigment itself may be an inhibitor of limited solubility.

##### 4.12.3.2.1 Basic pigments

Typical pigments in this class include basic lead carbonate, basic lead sulfate, red lead, and zinc oxide.

It has been established that water becomes non-corrosive after contact with paints prepared by grinding basic pigments in linseed oil,<sup>14</sup> it was also shown that lead and zinc linoleates, prepared by heating the oxide with linseed oil fatty acids in xylene, behave in a similar way. Later, this observation was extended to the linoleates of calcium, barium, and strontium.<sup>15</sup>

Determinations have been made of the solubility of lead linoleate prepared in the absence of oxygen and extracted with air-free water.<sup>16</sup> Under these conditions, lead linoleate had a solubility of 0.002% at 25 °C, and the extract was corrosive when exposed to the air. However, when the extraction was carried out in the presence of air, the resulting extract contained 0.07% solid material and was noncorrosive. It was concluded that in the presence of water and oxygen lead linoleate yielded soluble inhibitive degradation products.

In order to obtain information regarding the composition of these degradation products, aqueous extracts of the lead soaps of the linseed oil fatty acids were analyzed, mainly by chromatography. The extracts contained formic acid 46%, azelaic acid 9%, and pelargonic acid and its derivatives 27%, the remaining 18% consisting of a mixture of acetic, propionic, butyric, suberic, pimelic, and adipic acids. It was shown that whereas the salts of formic acid were corrosive, those of azelaic and pelargonic acid were very efficient inhibitors.

Mayne and Ramshaw<sup>17</sup> have obtained information regarding the origin of these various acids by examining the degradation products of the lead soaps of the individual acids present in linseed oil. They found that it was only the unsaturated acids which degraded

to give inhibitive materials, and that the lead soaps of linoleic and linolenic acid yielded in addition short-chain acids which were corrosive. He also examined the relative inhibiting powers of the lead, calcium and sodium salts of a range of mono- and dibasic acids in the pH range 4–6 at concentrations of  $10^{-3}$  to  $10^{-5}$  M.<sup>18</sup> Under these conditions the lead salts were always more efficient than the sodium and calcium salts, and the optimum efficiency occurred when both the mono- and dibasic acids had a chain length of 8–9 carbon atoms.

The mechanism of inhibition by the salts of the long-chain fatty acids has been examined.<sup>19</sup> It was concluded that in the case of the lead salts, metallic lead was first deposited at certain points and that at these points oxygen reduction proceeded more easily. Consequently, the current density was kept sufficiently high to maintain ferric film formation; in addition, any hydrogen peroxide present may assist in keeping the iron ions in the oxide film in the ferric condition, consequently the air-formed film is thickened until it becomes impervious to iron ions. The zinc, calcium, and sodium salts are not as efficient inhibitors as the lead salts and recent work has indicated that inhibition is due to the formation of ferric azelate, which repairs weak spots in the air-formed film. This conclusion has been confirmed by the use of  $^{14}\text{C}$ -labelled azelaic acid, which was found to be distributed over the surface of the mild steel in a very heterogeneous manner.<sup>20</sup>

Zinc phosphate was introduced as an inhibitive pigment by Barraclough and Harrison,<sup>21</sup> and in the early tests, vehicles based on drying oils were used. Later, it was claimed<sup>22</sup> that it was an effective inhibitive pigment when used with all paint media in current use.

Variable results have been reported with this pigment and an examination of its inhibitive action<sup>23</sup> has led to the conclusion that under rural and marine conditions, where the pH of the rainwater is above 5, it behaves as an inert pigment owing to its limited solubility. However, in industrial and urban areas, where the pH of the rainwater may be in the region of 4 or lower, it is converted into the more soluble monohydrogen phosphate. This reacts, in the presence of oxygen, with the steel surface to form a mixture of tribasic zinc and ferric phosphates, which being insoluble protects the steel from further attack.

##### 4.12.3.2.2 Soluble pigments

The most important pigments in this class are the metallic chromates, which range in solubilities from

17.0 to  $0.00005 \text{ g l}^{-1}$  as  $\text{CrO}_3$ .<sup>24</sup> An examination has recently been carried out of the mechanism of inhibition by chromate ions and it has been shown by chemical analysis of the stripped film, Mössbauer spectroscopy and electron microprobe analysis that the air-formed film is reinforced with a more protective material in the form of a chromium-containing spinel.<sup>25</sup> The situation is, however, complicated by the possibility that some chromates, particularly the basic ones, may inhibit through the formation of soaps. There is evidence that lead chromate can function in this way.

It has been found that red lead, litharge, and certain grades of metallic lead powder render water alkaline and inhibitive<sup>14</sup>; this observation has been confirmed by Pryor.<sup>26</sup> The effect is probably due to a lead compound, for example, lead hydroxide, in solution. Since, however, atmospheric carbon dioxide converts these lead compounds into insoluble basic lead carbonate, thereby removing the inhibitive materials from solution, these pigments may have only limited inhibitive properties in the absence of soap formation.

Work by Beckmann<sup>27</sup> indicated that lead hydroxide was only very slightly better as an inhibitor than sodium hydroxide, and the mechanism of inhibition is probably similar to that suggested for alkaline solutions.<sup>28</sup>

Owing to the low dielectric constant of organic vehicles, these pigments can ionize only after water has permeated the film; consequently, their efficiency is associated with the nature of the vehicle in which they are dispersed, a point which is sometimes overlooked when comparing the relative merits of chromate pigments.

#### 4.12.3.3 Resistance Inhibition

It has been shown that paint films are so permeable to water and oxygen that they cannot affect the cathodic reaction, and that the anodic reaction may be modified by certain pigments. There are, however, many types of protective paints which do not contain inhibitive pigments. It is concluded that this class of paints prevents corrosion by virtue of its high ionic resistance, which impedes the movement of ions and thereby reduces the corrosion current to a very small value.

It is assumed that conduction in polymer films is ionic; it is difficult to see how it could be otherwise. The factors which break down the ionic resistance, or render it ineffective, will now be considered.

The effective resistance of paint films may be influenced by ions derived from three sources:

- (a) electrolytes underneath the film;
- (b) ionogenic groups in the film substance;
- (c) water and electrolytes outside the film, that is, arising from the conditions of exposure.

##### 4.12.3.3.1 Electrolytes underneath the film

Atmospheric exposure trials, carried out in Cambridge, established the fact that when rusty specimens were painted in the summer, their condition, after some years' exposure, was very much better than that of similar specimens painted in the winter.<sup>29</sup> It was found that steel weathered in Cambridge carried spots of ferrous sulfate, deeply imbedded in the rust, and that the quantity of ferrous sulfate/unit area was very much greater in the winter than in the summer<sup>30</sup>; this seasonal variation was attributed to the increased sulfur dioxide pollution of the atmosphere in the winter, caused by the combustion of coal in open grates. It was concluded that there was a causal relationship between the quantity of ferrous sulfate and the effective life of the paint. It was suggested that these soluble deposits of ferrous sulfate short-circuit the resistance of the paint film, and since paint films are very permeable to water and oxygen, the ferrous sulfate will become oxidized and hydrolyzed with the production of voluminous rust, which will rupture the film at numerous points, thus giving rise to the characteristic type of failure seen on painted rusty surfaces.

It can be claimed that the problem of painting rusty surfaces is now understood. A method for estimating the ferrous sulfate content of any rusty surface has been put forward,<sup>30</sup> but the amount of ferrous sulfate which can be tolerated by various paints has not yet been established. Thus, it is a bad practice to apply paints to surfaces carrying electrolytes.

##### 4.12.3.3.2 Ionogenic groups in the film substance

Ionogenic (ion-producing) materials may be present, in the form of electrolytes, in both the pigments and the vehicle. Their presence in the pigments may be eliminated by the selection of suitable raw materials by the paint manufacturer; though it does not concern us here, it is important to consider the possibility of the existence of ionogenic groups, such as carboxyl groups, in the polymer itself.

When paint films are immersed in water or solutions of electrolytes, they acquire a charge.

The existence of this charge is based on the following evidence. In a junction between two solutions of potassium chloride, 0.1 and 0.01 M, there will be no diffusion potential, because the transport numbers of both the  $K^+$  and the  $Cl^-$  ions are almost 0.5. If the solutions are separated by a membrane equally permeable to both ions, there will still be no diffusion potential, but if the membrane is more permeable to one ion than to the other a diffusion potential will arise; it can be calculated from the Nernst equation that when the membrane is permeable to only one ion, the potential will have the value of 58 mV at 20 °C.

It is easy to measure the potential of this system and it has been found<sup>31</sup> that membranes of polystyrene, linseed oil, and a tung oil varnish yielded diffusion potentials of 43–53 mV, the dilute solution being always positive to the concentrated. Similar results have been obtained with films of nitrocellulose,<sup>32</sup> cellulose acetate,<sup>33</sup> alkyd resin, and polyvinyl chloride.<sup>34</sup>

This selective permeability is ascribed to the presence on the membrane of a negative charge, which is attributed to carboxyl groups attached to the polymer chains. Paint films can, therefore, be regarded as very large anions.

It has been shown that the charge influences the distribution of the primary corrosion products, and work<sup>35</sup> has indicated that the existence of carboxyl groups in the polymer film has an important influence on its behavior when immersed in potassium chloride solutions.

#### **4.12.3.3.3 Water and electrolytes outside the film**

Here, we are concerned with the effect of ions in the environment on the resistance of polymer films.

Kittelberger and Elm<sup>36</sup> measured the rate of diffusion of sodium chloride through a number of paint films. Calculations based on their results<sup>31</sup> showed clearly that the rate of diffusion of ions was much smaller than the rate of diffusion of either water or oxygen. Furthermore, they found that there was a linear relationship between the rate of diffusion and the reciprocal of the resistance of the film. This relationship suggests that sodium chloride is diffused through the membrane as ions and not as ion pairs, since the diffusion through the film of unionized material would not affect the resistance, because if a current is to flow, either ions of similar charge must move in one direction, or ions of opposite charge must move in opposite directions.

An examination has, therefore, been made of the effect of solutions of potassium chloride on the electrolytic resistance of films cast from a pentaerythritol alkyd, a phenolformaldehyde tung oil, and an epoxy-polyamide varnish.<sup>37,38</sup> Potassium chloride was chosen because its conductivity is well known and unpigmented films were first examined in order to eliminate the complexities of polymer-pigment interaction.

The experimental procedure consisted of casting the varnish on glass plates by means of a spreader bar having a gap of 0.102 mm; this produced a wet film of thickness 0.051 mm that yielded a dried film of 0.025 mm. This standard thickness was used throughout and resistances are quoted in  $\Omega\text{cm}^2$ . The cast films were dried for 48 h in a glove box followed by a further 48 h in an oven at 65 °C.

The films were then soaked in water and removed from the plates. Portions were mounted in glass cells which were filled with potassium chloride solution; two Ag/AgCl electrodes were inserted into the limbs of the cells and the unit was placed in a thermostat. The resistance of the films was determined, from time to time, by connecting the cells in series with a known resistance and applying a potential of 1 V to the combination; the potential drop across the standard resistance was measured by means of a valve potentiometer.

When samples of about 1 cm<sup>2</sup> were taken from a single cast film of 100 × 200 mm<sup>2</sup> of a number of paint and varnish films, their resistances varied with the concentration of potassium chloride solution in one of two ways (Figure 1). Either the resistance increased with increasing concentration of the electrolyte (inverse or I conduction) or the resistance of the film followed that of the solution in which it was immersed (direct or D conduction). The percentage of I and D samples taken from different castings varied, but average values for a number of castings were 50% D for the pentaerythritol alkyd and the tung oil phenol formaldehyde varnishes, 57% for urethane alkyd, 76% for epoxypolyamide, and 78% for polyurethane varnishes.<sup>39</sup>

The effect of iron oxide, zinc oxide, and red lead on the percentage of D areas has been determined. Three vehicles were used, a pentaerythritol alkyd, a tung oil phenolic, and an epoxypolyamide.<sup>40</sup> In the case of iron oxide, the D areas increased with all the three vehicles; in contrast, zinc oxide had very little effect on the percentage of D areas. However, red lead when dispersed in the alkyd and tung oil vehicles behaved in a similar way to iron oxide, whereas red

lead when dispersed in the epoxypolyamide vehicle had very little effect.

A careful examination has been made of the properties of I films when immersed in solutions of

**Figure 1** Relationship between the logarithm of the resistance of D and I films of a pentaerythritol alkyd paint, containing 6.1% iron oxide by volume, and the concentration of the potassium chloride solutions in which they were immersed. Reproduced from *Brit. Polym. J.* **1971**, 3, 41.

electrolytes. It was found that when a film of a pentaerythritol alkyd varnish was transferred from 0.001 to 3.5 N KCl its resistance rose, fell upon returning it to the 0.001 N KCl, rose again to the same high value when immersed in a sucrose solution isotonic with 3.5 N KCl and fell to the original value when returned to the dilute KCl solution (Figure 2). It was concluded that the changes in resistance were dependent only upon the available water in the solution and were associated, therefore, with the entry of only water into the varnish film.<sup>37</sup>

In contrast, D films followed the resistance of the solution in which they were immersed, and this behavior was originally explained by assuming that D films contained holes, or pores, filled with solution that controlled the resistance of the film. Thus, a typical value for the resistance of a D film in 3.5 M potassium chloride is  $108 \Omega \text{ cm}^2$  and if this resistance was due to a pore, then it would have a radius of about 50 nm. In order to test this explanation, the distribution of I and D areas in a given piece of film has been determined by means of a series of gaskets fitted into a dismountable cell.<sup>41</sup> It was found that I films were free from D areas, but in the case of the three vehicles examined, samples of D films always contained a mixture of I and D areas in an interlocking mosaic structure. It was concluded that those portions of the film having D properties were distributed over an appreciable area of the sample and not confined to a single area, as would have been the case had the sample contained a single pore.

**Figure 2** Relationship between the resistance of an I film (log scale) and the concentration of the solute. Reproduced from *Official Digest* **1970**, 34(452), 972–990.

It was concluded that D conduction cannot be attributed to the presence of pores, unless they were of molecular dimensions.

In general, the water uptake of D films tended to be higher than that of I films, but a more significant difference was shown by microhardness measurements. The results obtained with all the three vehicles showed that the D areas were significantly softer than the I areas and that the distribution of the hardness values corresponded to that of the resistances. It was concluded that these films have a very heterogeneous structure and that I and D areas are brought about by differences in cross-linking density within the film.

An investigation has been made of the factors that control I and D conduction and it has been found that the difference is only one of degree and not of kind.<sup>42</sup> Thus, if the varnish films are exposed to solutions of decreasing water activity, then the resistance falls with increasing concentration of electrolyte, but a point is eventually reached when the type of conduction changes and the films exhibit I-type behavior. It appears that D films can be converted into I films, the controlling factor being the uptake of water.

The discussion so far has been limited to the behavior of polymer films after immersion in potassium chloride solutions for only a short time. When varnish films were immersed in potassium chloride solutions for a month or more, a steady fall in resistance took place. Further experiments indicated that the effect was reversible and dependent on both the pH of the solution and the concentration of potassium chloride. It was concluded that an ion-exchange process was operative.<sup>37</sup>

In view of this, the properties of I films were examined after they had been subjected to increasing amounts of ion exchange.<sup>38</sup> In order to do this, detached films were exposed at 65 °C for 7 h to a universal buffer adjusted to a suitable pH and the resistance of the film measured at 25 °C in 3 M and 0.001 M potassium chloride. The results obtained with a pentaerythritol alkyd are shown in Figure 3 from which it can be seen that as the pH of the conditioning solution increased, the resistance of the film fell, until at a pH of about 7.5 when it suddenly dropped. The resistance of the film then followed that of the solution in which it was immersed, that is, it became a D-type film. Similar results were obtained with films of a tung oil phenolic varnish, although in this case the change-over point occurred at a higher pH, that is, about 9.

In the case of the epoxypolyamide varnish, however, as the pH increased the resistance of the film at

**Figure 3** Variation of the resistance of I films (log scale) with the pH of the conditioning solutions.

first rose, then at about pH 8.8 it started to fall until at pH 11 the change-over in the type of conduction occurred. This suggests that the resin was acting as a zwitterion with an isoelectric point at about pH 8.8. Thus, before the isoelectric point, the membrane would be positively charged and an increasing concentration of hydroxyl ions would depress the ionization of the ionogenic groups; above the isoelectric point, the membrane would be negatively charged and ion exchange with potassium ions would take place. This conclusion was confirmed by diffusion potential measurements.

In the case of all the three varnishes, after the ion exchange had taken place, a point was reached when the type of conduction changed from I to D. The change-over in the type of conduction was found to occur at the same pH as a fall in the temperature coefficient of resistance, and the lower value corresponded to that of the aqueous solution.

The phenomenon of ion exchange has been confirmed by chemical analysis.<sup>43</sup> Films were exposed to potassium chloride solutions of increasing pH, ashed and their potassium content determined by flame photometry. It was found that the potassium content of the films increased as the pH of the solutions rose until saturation was reached at a value which corresponded to that of the change-over in the mechanism of conduction. It was concluded that the change-over in the mechanism of conduction corresponded to the

point at which the exchange capacity of the film had reached its limit.

Rothwell<sup>44</sup> found by resistance measurements that ion exchange occurred in films of eight unpigmented varnishes, and he confirmed this for pentaerythritol alkyd films by the determination of the uptake of radioactive potassium in the form of  $^{42}\text{KCl}$ ; however, his films, with one exception, were all D type.

Fialkiewicz and Szandorowski<sup>45</sup> examined the penetration of  $^{90}\text{Sr}$  and  $^{36}\text{Cl}$  ions through air-dried films of a styrenated alkyd pigmented with iron oxide over the range 10–60% PVC (pigment volume concentration) and found intense penetration of the strontium cations, but negligible penetration of the chloride ions.

Ulfvarson *et al.*<sup>46</sup> examined the ion exchange properties of free films of a soya alkyd, and later Khullar and Ulfvarson<sup>47</sup> extended the examination to clear films of 20 vehicles. They concluded that those binders with low ion-exchange capacities provided the best protection. In a later study,<sup>48</sup> they examined the relationship between ion-exchange capacity and corrosion protection of 22 paints based on three alkyd binders and concluded that ion exchange was not the dominating factor, but a secondary one. This conclusion was confirmed by van der Heyden,<sup>49</sup> who suggested that a process of ion exchange combined with diffusion of cations into the film was operative.

#### 4.12.3.4 Physical Factors Affecting Resistance

##### 4.12.3.4.1 Temperature

An examination has been made of the effect of temperature on the structural changes in polymer films produced from the three vehicles described earlier.<sup>50</sup> Three methods were used: dilatometry, water absorption, and ionic resistance. It was concluded that dilatometry was the most reliable method and water absorption is difficult to determine. Both methods use appreciable quantities of film, which contain both D and I areas. Resistance measurements, however, can be carried out on small areas of film and the relative properties of D and I areas studied.

It was established that significant changes in resistance took place at the transition temperature and consequently sharp changes in protective properties. The resistance always fell with an increase in temperature and this may provide an explanation for the fact that accelerated tests using the same corrosion cycle may not produce the same results if carried out at different temperatures.

##### 4.12.3.4.2 Concentration of electrolyte

Myer and Sievers<sup>51</sup> applied the Donnan equilibrium to charged membranes and developed a quantitative theory of membrane selectivity. They expressed this selectivity in terms of a selectivity constant, which they defined as the concentration of fixed ions attached to the polymer network. They determined the selectivity constant of a number of membranes by the measurement of diffusion potentials. Nasini *et al.*<sup>52</sup> and Kumins<sup>53</sup> extended the measurements to paint and varnish films.

When the Donnan equilibrium is operative, the entry of ions into the membrane is restricted. Consequently, as the concentration of ions in the solution increases the resistance of the membrane remains constant until the concentration of ions in the solution reaches that of the fixed ions attached to the polymer network. At this point, their effect will be swamped and the movement of ions will be controlled by the concentration gradient.

Films of a pentaerythritol alkyd, a tung oil phenolic and an epoxy–polyamide pigmented with iron oxide in the range 5–7% PVC were exposed to solutions of potassium chloride in the range 0.0001–2.0 M.<sup>54</sup> It was found that in all cases, the resistance of the films steadily decreased as the concentration of the electrolyte increased. Since the resistances of the films were at no time independent of the concentration of the electrolyte, it was concluded that the Donnan equilibrium was not operative and that the resistance of the films were controlled by the penetration of electrolyte moving under a concentration gradient.

##### 4.12.3.4.3 Film thickness

Varnishes prepared from the three standard polymers were cast on two thicknesses and the percentage of D areas compared with that obtained from the films produced by casting one thin coat, allowing it to dry and then casting a second coat on top.<sup>59</sup> Similar results were obtained from all the three varnishes and the results obtained with the epoxy–polyamide varnish are given in Table 3.

**Table 3** Percentage of D areas on cast films epoxy–polyamide varnish

	Thickness ( $\mu\text{m}$ )	% D-type
Single coat	35–40	80
Single coat	75–80	50
Double coat	70–75	0–5

Earlier, it was shown that D type areas are relatively small; consequently, the chance of D areas overlapping each other is low. It follows that two coats of all the three varnishes, which are based on cross-linking polymers, are more effective in improving the resistance of the films than single coats of equal thickness.

#### 4.12.3.4.4 Solvents

All the films discussed so far have been cast from paints or varnishes containing solvents. In order to examine the effect of solvents, films of a solvent-free epoxy-polyamine were cast, mounted in cells, and their resistances measured in dilute and concentrated potassium chloride solution.<sup>55</sup> All the films had I properties with resistances in the range  $10^{10}$ – $10^{12} \Omega \text{ cm}^2$ .

It appears that during the drying of paint or varnish films, the presence of solvent molecules interferes with the process of cross-linking; consequently, the films have a heterogeneous structure and films of improved protective quality arise when solvents are eliminated.

It is suggested that future work should be directed toward the pigmentation of solvent-free systems, either with inert pigments, when they would form coatings of high electrolytic resistance which would protect by the exclusion of ions, or as sealing coats applied over primers containing inhibitive pigments.

### 4.12.4 Prediction of Paint Performance

If protection by paints or varnish films is due to their ability to restrict the penetration of corrosive ions, then it follows that resistance measurements should form the basis of the prediction of their behavior. In 1948, Bacon *et al.*<sup>56</sup> measured the resistance of over 300 paint systems immersed in seawater using a direct current (DC) technique, and concluded that for good performance, coatings should have a resistance in excess of  $10^8 \Omega \text{ cm}^2$ . Coatings having resistances in the range  $10^6$ – $10^8 \Omega \text{ cm}^2$  were found to be unreliable, and those of lower resistance behaved poorly.

It has frequently been suggested that during direct current measurements the specimens become polarized, consequently alternating current (AC) should be used. A comparison of DC and AC methods has been made and it was found that at a frequency of 1592 Hz and over the range 0.2–20 kHz, the values of the resistances were always lower when AC was used.<sup>57</sup>

The situation has now been clarified,<sup>58</sup> and it has been shown that, with AC, the values obtained are

controlled by the capacitance until the frequency has fallen to about 1 Hz. It was shown that under these circumstances, in the absence of corrosion, the resistances of paint films measured by DC or AC were the same; furthermore, no polarization resistance was detected.

The conclusions are that when coatings have resistances greater than  $10^8 \Omega \text{ cm}^2$  (i.e., when corrosion is absent) then their resistances may be measured by either DC or AC. However, DC measurements can be made more quickly; they are easier to make and the apparatus is less costly. It has also been suggested that such measurements provide a basis for the prediction of performance. On the other hand, when corrosion starts, the AC should be used, since the values obtained can be resolved into two components, which provide a means of detecting and following the corrosion beneath the coating.

**VCI** Volatile corrosion inhibitor

#### 4.13.1 Introduction

There are many temporary protectives in the market and it would be impracticable to describe them individually. However, they may be classified according to the type of film formed, that is, soft film, hard film, and oil film; the soft film may be further sub-divided into solvent-deposited thin film, hot-dip thick film, smearing, and slushing types. All these types are removable with common petroleum solvents. There are also strippable types based on plastics (deposited by hot dipping or from solvents) or rubber latex (deposited from emulsions); these do not adhere to the metal surfaces and are removed by peeling. In addition, there are volatile corrosion inhibitors (VCI) consisting of substances, the vapor from which inhibits corrosion of ferrous metals. The types of temporary protectives in common use are given in [Table 1](#).

#### 4.13.2 Types of Temporary Protectives

##### 4.13.2.1 Soft-Film Materials

Protectives that are deposited in the cold from a solvent usually consist of waxy substances such as

lanolin or petrolatum mixtures dissolved in solvents such as white spirit. Films formed in this way are thinner than other soft films deposited by different methods. On the other hand, protectives applied by dipping the article in the hot molten material are usually based on petrolatum.

Corrosion prevention depends largely on the barrier provided by the film, but for improved protection, corrosion inhibitors such as sodium nitrite or benzoate may be added. The film may be relatively hard and waxy or quite soft like pharmaceutical petroleum jelly. Corrosion-inhibited petroleum-based waxes deposited from solvent find application for the supplementary protection of hollow sections of finished products. These waxes are applied by airless or air-assisted pressure-feed spraying techniques to clean and dry, but often painted, surfaces to provide increased protection against corrosion due to humid and corrosive atmospheres during both transit and use.

The smearing types of protective material usually consist of lubricating grease compositions, that is, blends of soaps and lubricating oil, but may be mixtures containing petrolatum, oil, lanolin or fatty material. They are softer than the hot-dip materials to permit cold application by smearing. Slushing compounds are a variant of the smearing types and possess some flow properties at room temperature. Thus, they can be brush applied and marks produced after application are reduced. Some materials contain solvent, so that they are free-flowing as applied, but stiffen when the solvent evaporates.

**Table 1** Types of temporary protective in general use

<i>Types of protective</i>	<i>Typical ingredients</i>	<i>Method of application</i>	<i>Properties of film</i>
Solvent-deposited hard film		Dipping spraying, brushing	Solid, thin, tough, nonsticky, removable by wiping with solvent
(a) ordinary grade	(a) Plasticised bitumens, plasticised resins, white spirit, coal tar naphtha, chlorinated solvents		
(b) water-displacing grade	(b) As (a) above together with water displacing agents		
Solvent-deposited soft films		Dipping, spraying, brushing	Solid, thin, greasy, removable by wiping with solvent
(a) ordinary grade	(a) Lanolin, petrolatum, with and without specific corrosion inhibitors and antioxidants, white spirit, coal tar naphtha, chlorinated solvents		
(b) water-displacing grade	(b) As (a) above together with water displacing agents		
Hot-dipping soft film	Petrolatum, lanolin, with and without specific corrosion inhibitors	Dipping in molten material	Solid, thick, waxy or greasy, removable by wiping with solvent or immersing in hot oil
Smearing	Metallic soap and mineral oil, soft petrolatum, lanolin (castor oil/lead stearate for rubber-containing components)	Smearing, brushing	Solid, thick, greasy, removable by wiping with solvent
Slushing	Metallic soap and mineral oil, oil-softened petrolatum, lanolin, small amounts of solvent	Smearing, brushing	As for smearing protective
Oil	Mineral oil, specific corrosion inhibitors and antioxidants	Dipping, rinsing, spraying	Liquid, thin, oily
Strippable			
(a) hot-dipping grade	(a) Ethyl cellulose, cellulose acetate butyrate, mineral oil, plasticiser, resins, stabilisers	(a) Dipping in molten material	(a) Solid, tough, nonadherent. Often leaves oily film with lubricating properties; film removed by stripping.
(b) cold-applied grade	(b) Vinyl copolymer resins, plasticisers, stabilisers, flammable or nonflammable solvents	(b) Spraying, dipping	(b) Solid, tough, nonadherent film, removed by stripping
Volatile corrosion inhibitor (V.C.I.)	Organic amino salts (e.g. dicyclohexylamine nitrite, cyclohexylamine carbonate)	From solution by spraying, as a powder by sprinkling, by wrapping with V.C.I. impregnated paper	Adsorbed, nonvisible film

#### 4.13.2.2 Hard-Film Materials

These were developed to facilitate handling after treatment and to avoid contamination of adjacent components. The films are deposited in the cold and should be tough and neither sticky nor brittle. The deposited films may be plasticized polymer resins, bitumens, etc. which are varied according to the subsidiary properties required, such as transparency and

color. The solvents used vary according to the solubility of the ingredients, drying-time requirements, flammability, and permissible toxicity in given circumstances. As with the soft-film solvent-deposited materials, the surface coverage is large, and for this reason, and because they can be applied at room temperature, hard and soft-film solvent-deposited protectives are widely used.

### 4.13.2.3 Oil-Type Materials

These are usually mineral oils of medium or low viscosity, which contain specific corrosion inhibitors and antioxidants. In spite of the relatively low protective properties of the fluid films, which are not nearly as great as those of the previously described solid films, these materials have an established field of use on the internal surfaces of tanks and assembled mechanisms, and where solid material or solvent cannot be tolerated.

### 4.13.2.4 Strippable Coatings

The most important of these to date are those applied by hot dipping. Many are based on polymer resins with comparatively high dipping temperatures ( $\sim 190^{\circ}\text{C}$ ). They rely mainly on the thickness ( $< 2\text{ mm}$ ) and toughness of the coatings for their extremely good protective properties. They have the added advantage of giving protection against mechanical damage so that little added packaging is required for transport. Reuse of the material is frequently possible. The disadvantages are the necessity for special dipping tanks and cost; the latter may, however, be offset by saving in packaging materials. Strippable films deposited from solvents in the cold are much thinner ( $0.05\text{--}0.25\text{ mm}$ ) than those from the hot-dip materials and their protective properties are generally not nearly so effective.

Strippable coatings based on such polymer resins as vinyl, acrylic, and polyethylene are finding increasing favor for applying to finished products to protect them during transit. These coatings offer excellent temporary protection against moisture, chemicals, and weathering and some stand up well to such fabricating techniques as bending and deep forming. The coatings are easy to apply and some are removed simply by piercing the film and peeling it off, others by washing away by applying an alkaline solution or solvent.

### 4.13.2.5 Special Materials

#### 4.13.2.5.1 Water displacing agents

These have been developed for special uses. For example, as petroleum-based materials harm natural rubber, greases based on castor oil are available for use on the steel parts of rubber bushes, engine mountings, hydraulic equipment components, etc. (but are not for use on copper alloys). Some soft-film solvent-deposited materials have water-displacing properties and are designed for use on surfaces which cannot be

dried properly, for example, internal combustion engine cooling systems, boilers, etc.

An application of this type of fluid is assistance in the removal of ingested salt spray from jet aircraft compressors and the neutralization of corrosive effects. Other types of water-displacing fluids are claimed to have fingerprint neutralizing properties or to be suitable for use on electrical equipment. Some oil-type materials serve temporarily as engine lubricants and contain suitable inhibitors to combat the corrosive products of combustion encountered in gasoline engines.

#### 4.13.2.5.2 Volatile corrosion inhibitors

Volatile corrosion inhibitors are a special type of protective, which when present as a vapor inhibit the corrosion of metals. They are generally used as an impregnant or coating on paper or synthetic film; as a powder, either loose or in a porous container; or in the form of a 5% (w/v) solution in nonaqueous solution (e.g., alcohol) with application by either swab or spray. Their effectiveness in preventing corrosion depends not only upon the inherent activity of the material but also upon their volatility and rate of release from the supporting medium. Being volatile, some form of enclosure is necessary for continued effectiveness, whether it is by the closing of orifices with bungs or overwraps when protecting internal surfaces, or by sealing the outer container for other packed stores. Volatile corrosion inhibitors should be used with caution in the presence of nonferrous metals which may be attacked, particularly in the presence of free water. Care should also be taken with painted surfaces and with some plastics and other organic materials which may become discolored or damaged.

### 4.13.3 Scope for Temporary Protectives

Temporary protectives against corrosion should be used only where removal is subsequently necessary for the fitting or the working of surfaces to which they are applied. For example, coatings are designed to protect packaged engineering materials against corrosion due to a humid atmosphere, in both rural and general industrial conditions, during transit and storage. Where conditions are severe, extra packaging may be required or, in the case of thick soft-film materials, extra thicknesses may be applied. The coatings are also often used to protect unpackaged spares during shelf storage.

In normal thicknesses, temporary protectives are unsuitable for outdoor exposure and they should be protected against gross liquid water by coverings or wrappings. The wax and grease-based thick-film materials will, however, give adequate protection outdoors if they are applied extra thickly. Protection cannot be expected if the surfaces remain in contact with waterlogged packing material.

Corrosion preventives should be applied to surfaces which are clean and dry or corrosion may well continue beneath the coating. Materials with special properties such as water displacement or the ability to neutralize fingerprints should not be used in place of drying and clean handling, but only where the application demands it.

#### 4.13.4 Causes of Failure

In practice it is usually difficult to establish the reasons for failure as a number of factors may be simultaneously responsible, such as (1) application of the protective to dirty surfaces, (2) carelessness in application, (3) inherent inadequacy of the material, (4) exposure to unreasonably severe conditions, and (5) inevitable difficulties in application. Point (3) includes inadequacy not only in protective properties but, in the case of the hard-film materials, in certain physical properties, for example, the film may become brittle and flake when handled, may remain too sticky and become contaminated with dirt or adhere to the wrapping paper more strongly than to the surface to be protected, may age to form an insoluble material and become difficult to remove, or may not remain flexible and adherent at low temperatures. Point (4) includes, for example, the use of soft-film materials in hot conditions at temperatures too near to their melting point. As regards (5), it may be difficult to avoid thin places in the film arising from contact with other surfaces during the process of application, drying-off of the solvent, or cooling; when such thinning occurs, good surface-active properties are advantageous. In this connection, it may be pointed out that scraping in transit and stacking and local thinning due to grit, dirt, etc. are common; it follows therefore that shelf storage of unpacked items should be avoided if possible.

#### 4.13.5 Application of Protectives

Application by dipping gives the most complete film, is the most economical in material, and is usually the

quickest for large quantities of articles. This method should be chosen whenever possible. Spraying is the next best. Brushing and hand-smearing should be adopted only when dipping or spraying is not feasible.

During the dipping process, articles with recesses should be rotated in the bath so that air can escape. Dipping baths should be kept covered when not in use to prevent contamination and, in the case of solvent-containing materials, to prevent concentration by evaporation of the solvent, as this would lead to excessive film thicknesses and long drying times. The composition of a bath of solvent-containing material should be checked periodically. Unaided evaporation of the solvent from solvent-deposited films is usual, but the process can be speeded up by blowing air over the articles or by gentle warming; the heating, however, should not be excessive.

During hot-dipping, film thickness can generally be varied by altering the temperature of dipping and the duration of immersion. The molten material will first chill on to a cold article put in the bath, the solid coating bridging small crevices. This may give sufficient protection, but it may be desirable for the article to attain the temperature of the bath so that the material will fully penetrate into all the crevices, for example, between the ball and race of a rolling bearing. The article may then be withdrawn, allowed to cool and given a further dip to build up the film thickness.

#### 4.13.6 Choice of Protective

Hard-film protectives can be applied to most types of single articles and are especially suitable in mass-production systems. They should not be applied to assemblies because the hard film is liable to cement mating surfaces together and considerable difficulty may arise in the removal of the protective film. This type of protective should be removed before the article is put into use.

The soft-film solvent-deposited type can be used broadly for the same purposes as the hard-film type. A grease-resistant wrapping is required as an inner wrapping (as for all soft-film types) in packaging. Grades of this material, consisting essentially of lanolin in a solvent, have been found to give better protection to packaged articles than some of the best available hard-film materials and are to be preferred for articles with very high precision surfaces. The film is usually dispersible in lubricating oil and it

is therefore not so important to remove it from surfaces when an article comes into use except when it has become contaminated with grit and dirt.

The thick soft films produced by hot dipping are suitable for highly finished as well as normal machined surfaces. Grades with drop-points substantially higher than 50 °C are preferable for tropical storage as, otherwise, marked softening and possible thinning of the protective film are likely to occur. These films can be applied to many types of assemblies, the chief exceptions being assemblies with inaccessible interiors that cannot readily be blanked-off and fine mechanisms where any residue might interfere with the free movement of parts or their subsequent lubrication with low viscosity oil. These films can also be used on parts which might be affected by the solvent from the thin or soft film protectives, but they should not be applied to items having plastics or leather components.

Greases are usually applied by brush or smearing; the brush must be sufficiently stiff to give intimate contact with the surface yet not so stiff as to leave deep brush marks. Greases should not be melted and therefore cannot be applied by dipping or spraying; also, no attempt should be made to dissolve them in a solvent for application. They are particularly useful where only part of the surface of the item requires protection, because of the ease of application by cold smearing. They can be used in this way also in conjunction with solvent-deposited protectives for assemblies of a low degree of complexity, by coating screw threads and filling clearance spaces before dipping the article in the solvent-containing protective. Grease films can be made thick enough to give the desired level of protection. Wrapping is desirable to protect the very soft film. Removal before use is chiefly for the purpose of removing grit and dirt.

The slushing material finds its most useful application on big machinery requiring protection of large areas during storage or during intervals of idleness in

machine shops. The effect of dust and dirt contamination should therefore be considered an important factor in assessing the quality of these materials.

The lower protective quality of oil-type materials largely restricts their use on internal surfaces of, for example, internal combustion engine cylinders, and gearbox and back-axle assemblies of motor vehicles. Such materials are widely used to fulfill the simultaneous functions of a protective and lubricating oil; for example, in machinery the protective can also serve as a lubricant during its initial period of use. The functions of corrosion inhibitor and hydraulic oil are also often combined. Oil-type materials are also used on small nuts, screws, and washers which cannot easily be protected by solid-film materials; in this case, protection must be reinforced by good packaging.

The hot-dip strippable coating is applicable when a high standard of protection from corrosion and mechanical damage is required, as on gauges and tools which so often have their working surfaces facing outwards. Assemblies must have orifices plugged so that molten material cannot penetrate during the dipping.

Volatile corrosion inhibitors are particularly useful when oil, grease or other adherent films are unsuitable. They should be used in conjunction with a primary wrap which should form as close an approach to a hermetically sealed pack as possible. They are widely used to provide protection to precision tools, moulds, and dies and also on a larger scale to car body components.

### Glossary

**Block** Modern ships are constructed in sections (called blocks). A typical block will contain 2000–3000 m<sup>2</sup> of steel which requires coating.

**Block join-up** After construction and coating, the block is transferred to the building dock where it is welded to other blocks to produce the ship.

**Boot top** Area on the outer hull, which is immersed when the vessel is loaded and is out of the water when the vessel is not carrying a load.

**Fender damage** Fenders are applied on the side of docks to prevent the ship impacting with the dock wall.

**Grit blasting** A high velocity jet of an abrasive material is directed at the steel substrate to remove rust and coating and to introduce a surface profile onto the steel substrate. The process can be automated (at Newbuilding) or manual.

**Hydroblasting** Surfaces are treated with a high-pressure jet of water which is capable of removing coatings.

**Slurry blasting** A variant on hydroblasting in which abrasive is added to the high-pressure water jet.

**Ullage space** Space above the cargo (crude oil) and the top of the tank.

### 4.14.1 Introduction and Overview of the Marine Industry

Providing effective corrosion protection on ships and other marine structures presents a major challenge. The structure, which is normally constructed from

mild steel, may be subject to continuous immersion, cyclic wet–dry exposure, and extremely aggressive environments, including many of the cargoes ships transport. Corrosion protection is primarily obtained through applying high-performance coatings that are specifically designed for use on the different vessel types and vessel areas.

The current world fleet comprises 94 936 vessels, of which 50 214 are cargo carrying.<sup>1</sup> The market is currently growing at 6.6% per annum. Market growth is primarily driven by the current high freight rates, major economic growth in Asia, increased demand for liquid natural gas (LNG) carriers, and regulations requiring the phasing out of single-hulled oil tankers by 2010. **Table 1** shows the percentage of the world fleet by class of ship, in terms of both the number of ships and gross tonnage.<sup>1</sup>

This chapter primarily focuses on coatings for the high gross tonnage vessel types, because these represent the largest area of steel requiring protection, and therefore the largest coating volumes. The coating of smaller vessels, such as yachts and other marine structures, offshore platforms, etc., will not be considered in this chapter.

There are a number of distinct areas on ships as indicated in **Figure 1**: ballast tanks, underwater hull,

**Table 1**     World fleet by class of ship

<i>Ship type</i>	<i>Market % (by number of vessels)</i>	<i>Market % (by gross tonnage)</i>
Fishing vessels	25	2

Passenger vessels/Ferries	7	4
Tankers, crude oil	3	22
Liquid gas carriers	1	4

**Figure 1**     Different areas on a ship.

cargo tanks (dry cargo, oil, chemicals), decks, topsides and superstructure, and the vessel interior. Each area presents different challenges to the coating system.

**Table 2** shows the area of steel that requires coating for the different areas on the largest type of double-hull oil tanker, a VLCC vessel.

Over the last 20 years, there have been major changes in shipbuilding processes, ship operational procedures, and the marine coatings market, for example,

- Increase in Newbuilding shipyard productivity and reduction in vessel build times through the introduction of high-speed welding and cutting techniques, automation of certain fabrication processes and the adoption of block stage construction, and coating processes. To be compatible with the new shipyard procedures, coatings require fast cure/drying characteristics and flexible overcoating intervals.
- Changes in ship design and in-service operation. Examples include: (1) the move from single-hull to double-hull oil tankers, driven by major pollution incidents associated with damage to single-hull tankers (e.g., Exxon Valdez, MIT Erika); double-hull tankers have a significantly increased (at least 2 times) ballast tank area<sup>2</sup> as indicated in **Figure 2**, (2) the increased use of high-tensile steel in ship construction, and (3) increased cargo loading and unloading rates on bulk carriers.
- Environmental and health and safety issues together with changes in legislation have lead to

**Table 2**     M<sup>2</sup> of steel in the different areas on a VLCC tanker

<i>Vessel area</i>	<i>m<sup>2</sup> of steel</i>
Ballast tanks	235 000
Underwater hull	37 000
Boot top area	1600
Topsides	4300
Decks	21 800

**Figure 2**     Ballast tanks on single-hull and double-hull oil tankers.

(1) a reduction in solvent emissions through the use of higher solids or waterborne coatings and (2) the gradual phasing out of a number of marine coating types, including coal tar epoxy anticorrosives and antifouling paints based on tin copolymers. The reduction in solvent emissions has increasingly resulted in a change from one pack thermoplastic to two-pack thermoset coatings.

- A trend toward higher performance coatings with a longer service life and a reduced frequency of coating maintenance, for example, the new International Maritime Organization (IMO) regulations relating to the coating of ballast tanks<sup>3,4</sup>; these regulations are intended to improve the corrosion protection obtained in this critical vessel area.

As a result, the types of coatings used in the marine market have changed significantly from the coating systems described in earlier reviews.<sup>5,6</sup>

Prevention of corrosion on ships is essential; corrosion is recognized as one of the key factors that contribute to the loss of vessels at sea. In 2006, 25 vessels accounting for 409 000 gross tones were lost at sea.<sup>7</sup> Corrosion reduces the steel thickness and structural integrity of the vessel. Studies have shown that the corrosion rates are highest in the ballast tanks<sup>8</sup> where steel losses in excess of 1 mm year<sup>-1</sup> can be observed in uncoated tanks. Given the clear link between corrosion and vessel safety, ship operations are regulated by the classification societies who establish and apply technical requirements for the design, construction, and in-service survey of vessels. Ships and the coatings applied to ships are subject to regular surveys, and where the required remedial action, that is, the replacement of steel or the coating system, becomes mandatory in order for the vessel to be maintained in class. Class renewal/surveys are carried out every 1–5 years; this requires dry-docking of the vessel, which provides an opportunity to carry out major refurbishment of the coating system.

In addition to the benefits with regard to reduced corrosion, the application of coating systems, which provide effective long-term protection, is also important financially. The steel areas coated and the volume of paint applied to ships are significant. A VLCC tanker at Newbuilding will typically need >200 000 l of paint with a paint cost in excess of \$1 million. Surface preparation and the application process further add to the costs. Although coatings are designed to have a long service life, breakdown does occur, and given that the average lifetimes of oil tankers and bulk carriers are 28 and 30 years, respectively,

coating systems will need to be reapplied during the vessel's lifetime. At major refurbishment, the surface preparation costs, for noncomplex areas such as the underwater hull, are of the order of \$8 m<sup>-2</sup> (for an Sa2 blast), while application costs are typically \$1 m<sup>-2</sup>, highlighting the high costs associated with the application of marine coatings and the importance of specifying the correct coating systems.

#### 4.14.2 Corrosion Breakdown of Marine Coatings and the Factors Influencing Coating Performance

Marine coatings are designed to provide different performance characteristics depending on the vessel type and vessel area:

- corrosion protection (all vessel areas);
- fouling control (underwater hull);
- damage resistance (cargo holds);
- chemical resistance (chemical tanks);
- decorative effect (topsides, superstructure).

Although the primary attribute of many coatings is not corrosion protection, it is important to recognize that degradation and failure of the coating, for example, a cargo hold or chemical tank coating, will lead to conditions that result in corrosion of the steel substrate. The types of coatings used on different vessel areas and the specific modes of in-service failure associated with the coatings will be discussed in [Section 4.14.4](#).

Considering the corrosion breakdown of coatings on ships, it is clear that there are a number of different failure mechanisms, including:

- *Through film breakdown.* Corrosion occurs through the film in the absence of any macroscopic defect. Breakdown is attributed to the presence of pores in the coating which act as pathways for the transport of ions to the coating–steel interface.<sup>9,10</sup> Academic studies<sup>10,11</sup> have clearly demonstrated that coatings do not act as effective barriers to oxygen and water transport and that ion transport normally determines the rate of corrosion.

All coatings will contain microscopic pores and defects that are produced during the application, film formation, and coating ageing processes. However, the presence of pores does not mean that through film corrosion breakdown is inevitable as evident by the fact that marine epoxy–amine anticorrosive coatings can remain free from visual

corrosion over a period of many years. The pore size and pore distribution are important factors as is the potential for the pores to become blocked with corrosion product, which retards the corrosion process. The onset of through-film corrosion after many years in-service is indicative of chemical or physical changes occurring in the coating, which reduce the coating's barrier properties and promote ion transport and corrosion breakdown.

- Blistering:** Osmotic blistering of coatings, subject to full or periodic immersion, is due to the presence of water-soluble ionic contamination on the steel surface prior to coating application or soluble material present in the coating, which migrates to the coating-steel interface. Osmotic blisters are usually relatively small; larger blisters are produced by electroendosmosis, which can occur when the growing blister contains a pore. Anodic and cathodic blisters, associated with active corrosion cells, can also be observed.
- Cathodic disbonding at areas of coating damage:** At sites of impact and abrasion damage where the coating is removed exposing the steel substrate, rapid corrosion takes place. The high pH environment associated with the cathodes in the corrosion cell has the potential to attack the coating-steel interface, leading to the loss of adhesion and disbonding of the coating. When cathodic protection systems are used, the rate of cathodic disbonding may increase as the entire defect will act as a cathode. The extent of disbonding can extend over significant distances, and where there are multiple sites of damage, this can result in complete disbonding of the coating. A number of factors have been shown to influence the rate of cathodic disbonding,<sup>12</sup> including the coating thickness, substrate type and pretreatment, type and concentration of electrolyte, oxygen concentration, potential at the cathode, and the temperature.
- Rust jacking:** This type of failure is observed toward the end of the coating life. Where corrosion products are produced below the coating, the increase in volume of the rust, typically by a factor of 10, acts to lever the coating from the steel substrate as shown in **Figure 3**.
 

Disbonding of the coating will further accelerate the corrosion process. A similar failure mode can be observed for the calcareous deposits produced at the steel-coating interface for coatings under cathodic protection.
- Cracking of coatings:** This is now recognized as one of the potential early failure modes of anticorrosive

**Figure 3** Rust jacking.

**Figure 4** Cracking of coating in a ballast tank.

coatings applied in ballast tanks.<sup>13,14</sup> Cracking, an example of which is shown in **Figure 4**, is primarily observed on welds, corners, stiffeners, and other structural areas where stress concentration occurs.

Once cracking has occurred exposing the steel substrate, rapid corrosion breakdown follows. A number of factors influence the cracking susceptibility of coatings, including the stresses and strains imposed on the ship structure during operation, the intrinsic mechanical properties (flexibility, etc.) of the coating, internal and thermal stresses developed in the coating, and the coating film thickness. Cracking can also be observed on the block join-up areas, which have been power tool prepared, suggesting that the surface profile on the steel and the coating-substrate adhesion are also important factors. However, a recent study of cracking on erection joint weld seams prepared to different

standards found that the coating properties had the greatest influence on the cracking susceptibility.<sup>15</sup>

Cracking of ballast tank coatings appears to have increased on moving from single-hull to double-hull tankers. This potentially reflects the increased use of lower thickness high-tensile steel plates in double-hull tankers and the associated increase in the flexibility of the ship structure.<sup>16</sup>

In developing coatings and coating systems to provide long-term corrosion protection on ships, it is important to recognize that the coatings' composition and intrinsic performance characteristics are only two of the factors which will determine the in-service performance of the coating. The corrosion protection obtained will be influenced by:

1. The quality of the surface preparation prior to coating application. It is essential that contaminants, which may adversely affect the coating adhesion or lead to osmotic blistering, are removed. Potential contaminants include oils and grease, moisture, weld spatter, welding and cutting fume, corrosion products, and water-soluble salts. A range of surface cleaning procedures are available: solvent cleaning, abrasive blasting, water washing, hydroblasting, and power tool preparation. The appropriate technique or techniques are selected based on the nature of the contamination, the vessel area, and the conditions under which the surface preparation is carried out (there are major differences in the surface preparation procedures adopted at Newbuilding and Maintenance and Repair). Paint manufacturers normally recommend that the level of water-soluble salts on the steel surface is below 50 or 100  $\mu\text{g cm}^{-2}$ , this is supported by a number of studies<sup>17</sup> noting that the salt type, coating type, and ship vessel area have an

influence on the blistering characteristics, and several authors have proposed that the salt level should be significantly lower. The profile introduced onto the steel, by abrasive blasting or power tool cleaning, improves both the coating-substrate adhesion and the anticorrosive performance of the coated steel, particularly with regard to resistance to cathodic disbonding. The blast profile is determined by the type of blasting media selected and the standard of blast cleaning carried out; the latter is specified in a number of international standards as indicated in [Table 3](#).

Typical blast profiles, measured as the average peak to valley distance are 80–120  $\mu\text{m}$  for steel grit and 50–70  $\mu\text{m}$  for steel shot.<sup>18</sup>

2. Selection of the correct coating type. From a corrosion protection perspective, important characteristics are: good barrier properties, good adhesion to steel, mechanical properties and stress behavior required to minimize in-service cracking of the coatings, and environmental stability (resistance to degradation on long-term exposure). Given the highly alkali environments associated with corrosion cells and cathodic protection systems, the coating should be resistant to saponification. Epoxy-amine anticorrosives are currently the corrosion protection coatings of choice, particularly for vessel areas (underwater hull, ballast tanks) subject to permanent or periodic immersion.
3. Control of the application and cure conditions. In the marine market, it is not possible to control the environmental conditions, and coatings must be designed to be tolerant to application under a range of temperatures and humidities. Application at relatively high temperatures ( $>40\text{ }^{\circ}\text{C}$ ) can cause problems with excessive solvent loss during

**Table 3** International standards for abrasive blasting

	<i>NACE (National Association of Corrosion Engineers)</i>	<i>Swedish Standard/ ISO SIS055900 (1967)</i>	<i>Japanese Shipbuilding Research Association – Standard 1984</i>
White metal (all millscale rust, foreign matter removed)	NACE #1	Sa3	JaSh3 or JaSd3
Near white metal (only traces of millscale, rust, foreign matter remain)	NACE #2	Sa2½	JaSh2 or JaSd2
Commercial blast (almost all millscale, rust, foreign matter removed)	NACE #3	Sa2	JaSh1 or JaSd1
Brush off blast (loose millscale, rust, foreign matter removed)	NACE #4	Sa1	–

Similar standards exist for hydroblasting, power tool, and hand tool preparation of the substrate.

spray application, which will adversely affect the flow characteristics of the applied paint and can result in poor coalescence of the paint droplets. Poor coalescence will potentially reduce the barrier properties of the coating and lead to early corrosion breakdown. For thermoset coatings, such as epoxy-amine systems, the rate of cure is significantly reduced as the temperature is lowered. If the coating enters service before an adequate degree of cure has been achieved, this can lead to early corrosion breakdown. So-called 'winter workable' epoxy-amine coatings have been developed, which are designed to cure rapidly at temperatures down to  $-5^{\circ}\text{C}$ . Although coatings are generally tolerant to variations in the relative humidity, it is important that the coatings are not applied onto steel surfaces where condensation has occurred. Paint application should not take place when the steel temperature is less than  $3^{\circ}\text{C}$  above the dew point. Air flow and ventilation, which is particularly important when coating enclosed areas such as tanks, can have a significant impact on the rate of solvent loss from the coating. If the coating has a high level of retained solvent on service entry, this can have an adverse effect on the in-service performance.

4. Control of coating thickness. If the coating is under-applied, this will reduce the barrier properties and potentially lead to early corrosion breakdown. Over-application of the coating, which frequently occurs when coating complex structures in confined areas, such as ballast tanks, can also have an adverse effect on performance. With increasing film thickness, the internal and environmental stresses developed in the coating will be higher, which increases the potential for cracking and loss of adhesion at the coating-steel interface. Overapplication will also increase the amount of retained solvent in the coating.

The coating of edges presents a further problem. Due to the difficulty of spraying coatings onto the edges and the surface tension driven flow of the coating away from the edge, achieving the specified coating thickness is difficult and in-service corrosion breakdown of coatings is often observed at edges. This is shown in [Figure 5](#).

Several approaches to improve the edge protection can be adopted:

- Changing the edge profile by grinding the edge.
- Brush or roller application of stripe coats of the paint to the cut edge. Normal practice for coating cut edges in a ballast tank would be

**Figure 5** Flow of paint away from an edge.

spray coat-stripe coat-spray coat-stripe coat. Stripe coating is also used to improve the coating thickness control on fillet welds.

- Formulation of the coating to improve edge retention. This involves modifying the rheological characteristics of the paint to reduce the surface tension driven flow.
5. Use of a cathodic protection system on vessel areas that are continuously or periodically immersed. Such systems are used on the underwater hull, ballast tanks, and in cargo holds, which are also ballasted. The cathodic protection system will significantly reduce corrosion of any exposed steel. At the exposed steel, the cathodic reaction produces hydroxide ions, which react with metal ions and  $\text{CO}_2$  in the seawater to produce an insoluble calcareous deposit, which provides a degree of protection to the steel. It should be noted that cathodic protection systems in ballast tanks do not protect when the tank is empty, which typically accounts for 50–60% of the vessels operation. The cathodic protection system needs to be correctly designed and operated, as overprotection can in itself lead to coating breakdown through blistering and calcareous deposit jacking.
  6. Effective maintenance of the coating. In vessel areas that are readily accessible to the ship's crew, coating breakdown due to corrosion can be routinely repaired. The ship operator will monitor the coating condition in other vessel areas and put in place a strategy to either repair or replace coatings that are showing a significant degree of breakdown. Major refurbishment of the coating may only be possible when the ship is in dry-dock.

### 4.14.3 Coating Processes in the Marine Market

#### 4.14.3.1 Newbuilding

The fabrication and coating processes at Newbuilding have been designed to increase productivity, lower costs, and reduce the build time for new vessels.

Ships are primarily constructed from hot-rolled steel. During the steel manufacturing process, a relatively thick (20–50  $\mu\text{m}$ ) oxide layer, referred to as mill scale, is produced on the steel surface. As the mill scale is cathodic to the steel, rapid pitting corrosion is observed where there are breaks in the scale layer. It is therefore essential that the mill scale is fully removed prior to coating application. The steel is normally blasted with shot to an Sa2½ standard, using an automated rotary or wheel blasting unit.<sup>19</sup> The blast profile introduced on the steel should be less than 100  $\mu\text{m}$  peak-to-valley, as a larger profile may lead to peak coverage issues when the low film thickness shop primer coating is applied. After blast cleaning, it is important to apply a protective coating, a shop primer, as soon as possible to avoid corrosion of the cleaned surface. In practice, the blasting and primer coating processes are carried out on the same automated pretreatment line and the coating application takes place immediately after blasting.

The shop primer coating, which is typically applied at 15–20  $\mu\text{m}$  thickness, must have the following performance characteristics in order to meet the requirements of the shipyard:

- Dry rapidly to allow handling of the coated steel within 2–3 min.
- Provide effective corrosion protection of the steel during the ship fabrication process. As the build cycle varies in different shipyards, the corrosion protection period required is typically between 3 and 9 months. The low film thickness coating of shop primer is formulated to effectively follow the contours of the 50–100  $\mu\text{m}$  profile on the steel introduced during the shot blasting process.
- Be compatible with high-speed cutting and welding processes and have no detrimental effect on the weld quality.
- Resistant to mechanical damage during fabrication.
- Overcoatable with the full range of marine coatings.

Historically, a number of different types of shop primers have been used: phenolic–polyvinylbutyral (PVB) primers, epoxy coatings pigmented with iron

oxide, inhibitor pigments, or zinc and zinc silicate coatings. The current market is, however, dominated by solvent-borne zinc silicate shop primers; this reflects (1) the improved cutting and welding characteristics obtained through the use of an inorganic binder system and (2) the enhanced corrosion protection. The zinc pigment galvanically protects the steel substrate and the zinc corrosion products produced, while providing protection, act to block pores in the coating, leading to an increase in the coating barrier properties.<sup>20</sup> Solvent-borne zinc silicate shop primers are two-pack coatings based on a prehydrolyzed tetraethyl orthosilicate binder system, the cure of which is acid catalyzed.<sup>19,21</sup> Unlike the high-build zinc silicate anticorrosive coatings used in the protective coatings market, the amount of zinc in the coating is kept as low as possible, while maintaining effective corrosion protection; this is because zinc can have an adverse effect on the welding process. Coatings are normally formulated above the critical pigment volume concentration (CPVC) and the applied coatings are therefore porous. The shop primer coating is applied using automated airless or high-volume low-pressure (HVLP) spray processes.

Solvent emission legislation, particularly in Europe and the United States, is impacting on the use of the high solvent content (typically 650 g l<sup>-1</sup>) zinc silicate shop primers. As it is difficult to formulate this type of product with higher solids, the Newbuilding shipyard has two options to reduce emissions: (1) to install solvent abatement equipment on the pretreatment line and continue to use the current solvent-borne products or (2) to move to an alternative low or zero solvent content shop primer. Although waterborne zinc silicate coatings are commercially available, the conventional formulations based on alkali silicate binders are unsuitable for use in the marine market because of their high water-soluble salt content and susceptibility to osmotic blistering when overcoated and immersed. New waterborne coatings, which overcome this limitation have recently been commercialized<sup>22</sup> or are under development. A further issue with the use of zinc silicate shop primers is the potential for the formation of zinc corrosion products (so-called white rust) on the coating surface. If overcoated, the corrosion products may produce a mechanically weak interface and adversely affect the in-service performance of the coating scheme. Normal shipyard practice is to carry out secondary surface preparation (sweep blasting with grit) to remove any white rust immediately

prior to applying subsequent coatings. Certain solvent-borne zinc silicate shop primers have been formulated to produce low levels of white rust, which allows direct overcoating without the need for secondary surface preparation.

The shop-primed steel plates and bars are cut and welded to produce subassemblies, and eventually, blocks. In high-productivity shipyards, the application of the main epoxy anticorrosive system and many of the other coatings takes place at the block stage. In certain shipyards, 80–90% of the coatings can be applied at the block stage. A typical block from a VLCC tanker is shown in [Figure 6](#).

Coating of the blocks is carried out indoors, allowing better control over the environmental conditions. Normal practice is to apply the full anticorrosive scheme, for example,  $2 \times 150 \mu\text{m}$  coats of epoxy plus stripe coating of welds and cut edges, followed by the cosmetic finish or antifouling paint. Coatings are airless spray applied. Although it is possible to apply different epoxy coatings onto different areas of the block, reflecting where the block will be positioned in the final ship construction, a current industry trend is the move to ‘universal primer’ coatings, which are designed for use on all areas of the ship, except certain specialist areas such as potable water and chemical tanks. The use of a universal primer simplifies the coating process, providing both time and cost savings. The coated blocks are subsequently transferred to the building

dock where they are welded together. Prior to applying coatings to the block join-up areas, the steel surface has to be prepared. Grit blasting cannot be carried out due to concerns over damaging the coatings already applied to the block, so the join-up areas are manually prepared using power tools and associated techniques. Following construction of the ship, any remaining coatings are applied; chemical tank coatings are always applied postconstruction and many shipyards choose to apply the antifouling paint and finishes at this stage.

#### 4.14.3.2 Maintenance and Repair

Although the cost of repairing coatings is relatively high, when the surface preparation, labor, and paint costs are considered, this cost is low in comparison with the cost of steel replacement, which would be required if extensive corrosion takes place.

Two different scenarios need to be considered: (1) major refurbishment of the vessel where the existing coating is either fully replaced or subject to significant repair and (2) on-board maintenance (OBM) where the ship's crew carries out routine repair of the coating on those vessel areas (decks, superstructure, certain areas in ballast tanks) that are readily accessible.

At major refurbishment, the coatings used are essentially the same as those applied at Newbuilding. The surface preparation procedures are, however, significantly different

**Figure 6** Block section from a VLCC.

- Due to the potential for high levels of salt contamination on the coating surface, thorough high-pressure water washing is essential prior to preparation of the surface.
- Although grit blasting continues to be widely used, concerns over the amount of dust (grit and removed coatings) released to the atmosphere have seen an increase in the use of hydroblasting and slurry blasting techniques.<sup>19</sup> Although hydroblasting is very effective at removing old coatings and cleaning corrosion pits, it is important to recognize that it does not introduce a new blast profile (the profile applied at Newbuilding is however retained) and the technique can also lead to flash rusting of the steel substrate.

Following the replacement of any heavily corroded steel, the removal of existing coatings, and surface preparation, the new coating scheme will be applied by airless spray. As at Newbuilding, stripe coating of cut edges and welds is essential.

The objectives of OBM are (1) to maintain the ship's appearance by periodically applying new finishes to the deck and superstructure and (2) to repair areas of coating breakdown and corrosion. Manual surface preparation, using power tools and discs, is carried out at sites of corrosion breakdown, but is generally confined to the areas of visible corrosion, leaving potential active corrosion cells under the intact coating. Finishes are normally applied directly over the existing coating scheme, which will be prepared by solvent degreasing (where required) and high-pressure water washing. One-pack alkyd finishes are widely used in this market and the application is by brush and roller. Alkyd and epoxy primers are used; these can be significantly different from the products used at Newbuilding and major refurbishment, and are designed to have improved surface tolerance (to damp and contaminated surfaces, residual rust, aged coatings) and for application under the variable environmental conditions encountered at sea. One important difference in the OBM market is that the coating systems used are not subject to any regulations on solvent emissions. Lower solids coatings can therefore be used in the OBM market.

#### 4.14.4 Coating Selection for Different Vessel Areas

##### 4.14.4.1 Underwater Hull

The coating system has two primary functions: (1) to provide effective corrosion protection on a vessel

area that is subject to permanent sea water immersion and (2) to prevent the attachment of marine organisms to the hull; fouling increases the hull's roughness and significantly reduces the vessel's fuel efficiency. Corrosion protection is provided by a combination of a high-build epoxy anticorrosive (refer to [Section 4.14.4.2](#)) and cathodic protection, using either an impressed current system or sacrificial zinc or aluminum anodes. As previously discussed, the cathodic protection system must be correctly designed and installed to avoid overprotection issues, which can lead to premature breakdown of the coating.

Antifouling coatings are classified as either biocidal or nonbiocidal foul release systems.

The biocidal coatings contain pigments, such as copper oxide, copper thiocyanate, and copper metal, which in the presence of seawater, produce biocidal copper ions. Organic booster biocides are also introduced to further improve the antifouling performance, particularly against slimes and weeds. The use of biocides is increasingly subject to regulatory review in Europe<sup>23</sup> and it is likely that the range of biocides approved for use in marine antifoulings will reduce in the future. Biocidal antifoulings are further classified in terms of the binder type<sup>24</sup>:

- *Self-polishing copolymers (SPC)*: At the coating–water interface, the binder undergoes controlled hydrolysis and is converted from a water-insoluble to a water-soluble polymer. The coating slowly dissolves and the dissolution process effectively maintains a constant rate of release of the biocide throughout the coating lifetime. The coating dissolution also reduces the coating roughness introduced during application and further improves the vessel's fuel efficiency. SPC antifoulings were originally based on acrylic copolymers of tributyltin-methacrylate; however, these coatings have now been phased out because of environmental concerns over the released tributyltin oxide (TBTO). Alternative binder systems based on metal (copper or zinc) acrylate and silyl ester polymers have recently been developed.
- *Controlled depletion polymers (CDP)*: An intrinsically water-soluble material, normally gum rosin, is blended with a water-insoluble vinyl or acrylic polymer. The advantage of this coating type is the lower solvent content. However, CDP antifoulings do not show the smoothing effect observed for SPC coatings and the in-service lifetime of CDP coatings is normally limited to 3 years rather than the 5 years achievable from SPC coatings.

- *Hybrid coatings:* Rosin and a self-polishing copolymer are combined.

Typical coating schemes applied on the underwater hull are summarized in [Table 4](#).

Biocidal antifouling coatings are one-pack solvent-borne coatings with solid volumes in the range 45–55% and typically contain up to 60 wt% biocidal pigments in the dry film.

The selection of the antifouling type and applied coating thickness is, in part, determined by the time period between dry-docking of the vessel, normally 2.5 or 5 years, depending on the classification society rules and the vessel activity. It is essential that the antifouling maintains effective performance throughout this period in-service.

At major refurbishment of the vessel, the underwater hull will either (1) be high-pressure washed, fully blasted, and recoated with both the anticorrosive and antifouling, or (2) be high-pressure washed, have areas of damage spot repaired, and a new coating of antifouling applied to the underwater hull.

Nonbiocidal foul release coatings were originally based on silicone elastomers.<sup>25</sup> The coatings are highly hydrophobic, low surface energy, low  $T_g$  materials, which present surfaces that are difficult to adhere to. If the coating remains static, fouling will occur; however, movement of the vessel causes release of the fouling. To be effective, the vessel should be operating at speeds in excess of 10 or 15 knots for >80% of its service life. As shown in [Table 4](#), the silicone antifouling comprises a silicone tie coat and a silicone topcoat, the topcoat being modified with a silicone fluid to optimize the foul release characteristics. Due to the low surface energy of the silicone coating, the coating cannot be applied directly to the epoxy anticorrosive, so hybrid epoxy–silicone tie coats containing adhesion promoters are used to obtain effective adhesion.

**Table 4** Typical coating schemes for the underwater hull

<i>Antifouling coating type</i>	<i>Coating scheme (dft)</i>	
Tin free SPC (60-month scheme)	Epoxy anticorrosive SPC antifouling	2×150 μm 3×125 μm
CDP (36-month scheme)	Epoxy anticorrosive CDP antifouling	2×150 μm 2×125 μm
Foul release coating	Epoxy anticorrosive Silicone tie coat Silicone or fluoropolymer finish coat	2×150 μm 1×100 μm 1×150 μm

Recently introduced fluoropolymer topcoats offer a further enhancement in the antifouling performance.

Foul release coatings are more expensive, on a \$ m<sup>-2</sup> basis, than the biocidal antifouling. However, significant through life cost benefits can be obtained. Major refurbishment costs are reduced; the normal procedure is to carry out only touchup repair and apply a further thin coat of the topcoat every 5 years.

The amount of corrosion breakdown observed on the underwater hull is normally relatively low; this reflects the fact that (1) the submerged areas are not subject to mechanical damage, (2) the antifouling paint prevents marine organisms adhering to and potentially damaging/removing the coating, and (3) the hull is cathodically protected. Corrosion breakdown primarily takes place at the waterline, the so-called Boot-top area on the vessel, because of a combination of the repeated wet–dry cycling of the coating, UV exposure, and fender damage.

The use of copper or copper oxide (which contains low levels of copper metal) pigmented antifouling paints can lead to severe pitting corrosion on aluminum hull vessels.<sup>26</sup> As copper has a more positive electrochemical potential than does aluminum, if there are defects in the epoxy primer system, a galvanic cell will be set up with the aluminum hull acting as a sacrificial anode.

#### 4.14.4.2 Ballast Tanks

The corrosion rates in ballast tanks, if left uncoated, are usually the highest of any vessel area.<sup>8</sup> This reflects the severity of the conditions experienced in ballast tanks, as the tank alternates between full immersion in seawater when in ballast and a high humidity environment when deballasted. The latter condition is more aggressive from a corrosion perspective, in part, because any cathodic protection system used in the ballast tanks will not be active. Ballast tanks are also subject to large variations in temperature, which can both accelerate corrosion and contribute to a premature breakdown of coatings through cracking and other processes. The increased ballast tank area in double-skin tankers and the structured complexity of the tanks, with many welds and edges, makes the effective protection of the tanks with coatings both essential and a major challenge. [Figure 7](#) shows a typical area in a ballast tank.

It is important that coatings applied at Newbuilding provide long-term protection as the cost of replacing the coating is potentially financially prohibitive;

**Figure 7** Interior of a typical ballast tank.

Mills<sup>2</sup> suggests that it would take 250 days and cost about \$20million to fully recoat a VLCC tanker with 250 000 m<sup>2</sup> of ballast tanks. This issue is currently being addressed, at least in part, by the new IMO ballast tank coating standard for Newbuilding,<sup>3,4</sup> which defines procedures for the design of the coating systems, surface preparation, acceptable application conditions, and the inspection of the applied coating. A coating service life of 15 years is targeted, which means that major refurbishment of the ballast tank coating will normally still be required during the vessel's lifetime.

The coating systems used in ballast tanks are almost exclusively based on epoxy-amine resins. The coatings are relatively high solids ( $\geq 70\%$  volume solids), solvent-borne systems. This coating type has a number of characteristics: excellent barrier properties, good adhesion to steel and shop primer, resistance to hydrolytic and high pH degradation, and potential for rapid cure under ambient conditions, which make it particularly suitable for use in ballast tanks and as a universal primer applied at Newbuilding. Epoxy ballast tank coatings contain a relatively high loading of barrier pigments such as mica and talc. Corrosion inhibitor pigments are not used due to concerns over the potential for osmotic blistering. The coating is normally light colored to make in-service inspection and the detection of the onset of corrosion easier. A number of different types

of epoxy-amine ballast tank coatings are available; all are based on aromatic, bisphenol A, or to a lesser extent, bisphenol F, epoxy resins:

- *Coal tar epoxy:* The epoxy-amine resin system is combined with a naturally occurring coal tar. A two-phase, heterogeneous, binder is produced, which is very hydrophobic. Although coal tar coatings have a long track record of providing excellent corrosion protection in ballast tanks, this type of product is currently being phased out due to (1) health and safety concerns over materials present in the coal tar, and (2) the dark color of the coatings.
- *Pure epoxy and modified epoxy coatings:* The distinction between the two coatings is that the modified epoxy coatings contain either (1) nonepoxy resins, for example, acrylate functional materials, which can react into the epoxy-amine binder, or more commonly, (2) nonreactive liquid or solid resins, typically hydrocarbons, which modify the properties of both the liquid and cured coating. A concern with the use of modified epoxy coatings is the potential for extraction of the nonreactive resin on long-term immersion. There has been considerable debate concerning the relative merits of pure and modified epoxy coatings,<sup>27,28</sup> the pure epoxy being claimed to have the better barrier properties and the modified epoxy improved tolerance to

application onto surfaces with reduced preparation. If correctly formulated, both coating types can provide good long-term anticorrosive performance.

- *Aluminum pigmented coatings:* The amount of aluminum flake pigment added to coatings has to be maintained at a relatively low level in the cured coating, typically less than 10 wt%, to avoid potential safety issues associated with the generation of sparks when the coating is subject to impact or abrasion. Aluminum pigmented epoxy coatings can provide excellent corrosion protection, and in particular, very good resistance to cathodic disbonding at defects. Although the lamellar aluminum flake pigmentation may improve the coating barrier properties, recent studies<sup>29</sup> have demonstrated that the aluminum pigment also reacts with the hydroxide ions produced at the cathodic sites in the corrosion cell.
- *Solvent-free epoxy coatings:* A recent development to address the increasing legislative restrictions on solvent emissions. To maintain an acceptable viscosity for application, the paints are normally formulated with a reduced level of pigmentation, may contain high levels of reactive or nonreactive diluents, and may require the use of heated application equipment.

A more detailed consideration of the coating chemistry and formulation guidelines can be found in other reference works.<sup>30,31</sup> In addition to epoxy-amine coatings, these references also discuss both the polyurethane and alkyd coating systems that are used on other vessel areas.

The epoxy-amine coatings are two-pack products, which are mixed immediately prior to application. Coatings are normally applied by airless spray. Typical coating schemes are indicated in **Table 5**.

Stripe coating of welds and cut edges, by brush or roller, is important if effective corrosion protection is to be achieved, and this is now a mandatory requirement in the new IMO coating regulations.<sup>3,4</sup>

Because of the wide range of temperatures experienced during application and cure of the coatings,

for example, in Korean Newbuilding shipyards, paints are applied at temperatures as low as  $-5^{\circ}\text{C}$ , epoxy coatings are often formulated in 'summer' and 'winter' versions. The type of amine curing agent and level of catalyst are varied in order to obtain the rapid cure characteristics required by the shipyard.

Cathodic protection systems based on sacrificial zinc or aluminum anodes are used in ballast tanks. The system is either installed at Newbuilding or can be introduced several years into the coating life; this largely depends on the vessel operator's preference.

Other approaches to improve the corrosion protection in ballast tanks are also being considered, including the use of deoxygenation of the ballast water<sup>32</sup> and the use of gas inertion systems.<sup>33</sup> Neither of these approaches is considered as a replacement for the coating system, but they may enhance the coating performance.

Given that the average life expectancy of ships is in excess of 25 years, repair and/or replacement of the ballast tank coatings applied at Newbuilding will be required. The coating systems and schemes outlined in **Table 6** are also applied at Maintenance and Repair. Other more surface and damp-tolerant epoxy and one-pack vinyl coatings have also been developed for the OBM market. An IMO standard for the maintenance of ballast tank coatings is currently under discussion.

Future IMO regulations, due to be implemented from 2009, will require the treatment of ballast tank water to prevent the transport of marine organisms between different geographic locations in the ballast water. A number of different treatment technologies, including electrolysis, UV radiation, addition of chemicals, and deoxygenating, are currently being proposed. There are concerns that the water treatments could increase the corrosion rates in ballast tanks,<sup>34</sup> and testing of the new technologies in conjunction with ballast tank coatings is required.

#### 4.14.4.3 Cargo Tanks

As indicated in **Table 1**, cargo tankers, which transport crude oil, account for 22% of the world fleet (considered as gross tonnage). Until recently, normal practice was to leave the cargo tanks uncoated, as the oil was considered to be a relatively inert material and the oil film remaining on the tank walls, on emptying the tank, provided a degree of corrosion protection.<sup>5</sup> However, corrosion was frequently observed in cargo tanks primarily at the top (the deck head) and on the floor (the tank top) of the tank, and the corrosion rates

**Table 5** Coating schemes for ballast tanks

Coating type	Coating scheme (dft)
Coal tar epoxy	$1 \times 250 \mu\text{m} + \text{stripe coat or } 2 \times 125 \mu\text{m} + 2 \text{ stripe coats}$
Modified and pure epoxy	$2 \times 125 \text{ or } 2 \times 150 \mu\text{m} + 2 \text{ stripe coats}$
Aluminum pigmented epoxy	$2 \times 125 \text{ or } 2 \times 150 \mu\text{m} + 2 \text{ stripe coats}$
Solvent-free epoxy	$1 \times 300 \mu\text{m} + 2 \text{ stripe coats}$

**Table 6** Coating systems for chemical and product tanks

Coating type	Typical scheme (dft)	End use/potential limitations
Epoxy-amine	2×125 µm or 3×80 µm or 3×100 µm	Primarily used for product carriage
Zinc silicate	1×100 µm	Cannot carry strongly acidic or basic cargoes Unsuitable for carriage of vegetable oils
High-performance epoxy (epoxy-isocyanate)	3×90 µm	Chemical carriage Relatively low solids products
Epoxy phenolic	3×100 µm	Chemical carriage To obtain optimum performance the coating needs to be postcured

were typically 2–3 times higher than those expected for uncoated steel.<sup>35</sup> Corrosion breakdown was primarily attributed to<sup>35</sup>

1. the low level of water in the crude oil, which on storage, settles to produce a thin layer below the oil. The water can have a strongly acidic pH due to water-soluble materials, such as sulfates, present in the oil;
2. microbial-induced corrosion, particularly associated with acid-producing bacteria (APB) and sulfate-reducing bacteria (SRB); and
3. corrosive materials present in the ullage space above the crude oil. Gases such as hydrogen sulfide can be released from the oil. The inert gas system, which is used to prevent the buildup of oil vapor in the ullage space, contains sulfur dioxide and nitrous oxides as well as other impurities.<sup>13</sup>

Factors (1) and (2) lead to the corrosion of the floor of the tank and can result in severe pitting of the steel.

More general corrosion breakdown is observed on the deck head.

Changes in ship design have also contributed to the increased rates of corrosion. Double-skin tankers retain the heat of crude oil (certain heavy crude oils are loaded into the tank at 80–100 °C) more effectively than do the older single-skin tankers and the higher temperature will accelerate any corrosion processes. The increased use of high-tensile steels has resulted in more flexible ships and the increased flexing of the structure acts to loosen scale and rust on the deck head, exposing a new layer of steel to the corrosive environment.<sup>36</sup> Vessels constructed from thermomechanically controlled process (TCMP) steel can also show increased susceptibility to pitting corrosion.<sup>35</sup>

Given the corrosion issues observed in cargo tanks, coatings are now normally applied to the top

and bottom 2–3 m of the tank. The rest of the tank is not coated with anything other than the low film thickness zinc silicate shop primer applied at Newbuilding. Coal tar epoxy coatings were very effective in cargo tanks due to their excellent acid resistance; however, this product type is being phased out due to health and safety concerns. Modified or pure epoxy-amine coatings, essentially the same coatings as applied in ballast tanks, are currently used in cargo tanks. The coating will be applied as a 2×125 or 2×150 µm film thickness scheme. The coatings provide long-term protection and will not normally be replaced during the vessel's 20–30 year lifetime. Proposed IMO regulations are expected to make the coating of the deck head and the top of cargo tanks mandatory at Newbuilding.<sup>37</sup> A potential amendment to the new regulations currently under discussion is the option of constructing the tank, or parts of the tank, from corrosion-resistant steels, which have improved resistance to the environments present in cargo tanks. The corrosion-resistant steel would not require coating.

#### 4.14.4.4 Chemical and Product Tankers

Although crude oil carriage represents by far the largest sector of the cargo tanker market, there has been an increasing trend toward shipping refined oil products (aliphatic hydrocarbons, gasoline, diesel, aviation fuel) and chemicals (organic and inorganic chemicals, vegetable oils/animal fats). Coating of the tanks on chemical and product tankers is essential; certain cargoes can chemically attack the steel, and after carriage of a cargo, the tank will be subjected to a rigorous cleaning regime, using water and often acidic or basic cleaning chemicals. If corrosion occurred in the tank, the corrosion products could contaminate the cargo.

High-performance coatings are used in the chemical and product tanker market. The coatings must be

resistant to the wide range of cargoes carried and impose minimum restrictions on the carriage of the subsequent cargoes. The coating should also exhibit low cargo absorption and/or any absorbed cargo should be rapidly desorbed during the venting and cleaning of the tanks between cargoes – this is important to avoid the absorbed cargo being desorbed into the next cargo, resulting in contamination. Obtaining good coating–substrate adhesion and accurate film thickness control are also essential; to achieve this, high-quality surface preparation and coating application are required. At Newbuilding, the chemical tank coatings are applied post vessel erection rather than at block stage, the entire tank is reblasted to an Sa2½ standard and the coating is applied under a defined range of environmental conditions (temperature, relative humidity).

As an alternative to coated tanks, the ship owner has the option of constructing the tanks from stainless steel. However, stainless steel is expensive, more difficult to fabricate and weld, and can still be attacked by certain chemicals (e.g., chlorides). As a result, most vessels use coated mild-steel tanks or a combination of mild and stainless steel tanks.

A number of different coating types can be used as shown in [Table 6](#).

The selection of the coating is largely dependent on the chemicals that will be carried. The epoxy–amine coatings, which are of the pure epoxy resin type discussed in the ballast tank section, provide very effective protection against refined oil products and certain chemicals. Cargo absorption is, however, an issue. Zinc silicate coatings, which can be either solvent-borne or waterborne, offer excellent chemical resistance together with low cargo absorption and cross contamination. However, this type of coating cannot be used for strongly acidic or basic cargoes because of the potential for rapid dissolution of the zinc pigmentation. The high-performance epoxy and epoxy phenolic coatings are designed to have polymer networks with very high crosslink densities to reduce cargo absorption. The epoxy–isocyanate coatings are relatively low solids due to the requirement to use hydroxide functional epoxy resins for reaction with the isocyanate, and certain owners also have health and safety concerns over the use of isocyanates. As a result, the market has increasingly moved to using epoxy–phenolic coatings for the most demanding applications. The epoxy–phenolic coatings, which are relatively high cost in comparison with the epoxy–amine and zinc silicate systems, produce a high crosslink density through a ‘dual cure’

mechanism. The epoxy phenolic resin is partially cured with an amine and the residual epoxy functionality is homopolymerized using a suitable catalyst. The homopolymerization reaction primarily takes place at elevated temperature (60–100 °C), and prior to the carriage of certain cargoes, the epoxy phenolic coating needs to be postcured. Postcure can be via heating with hot-air blowers or applying hot water onto the coating through the tank cleaning system; alternatively, the carriage of heated cargoes can produce an effective postcure.

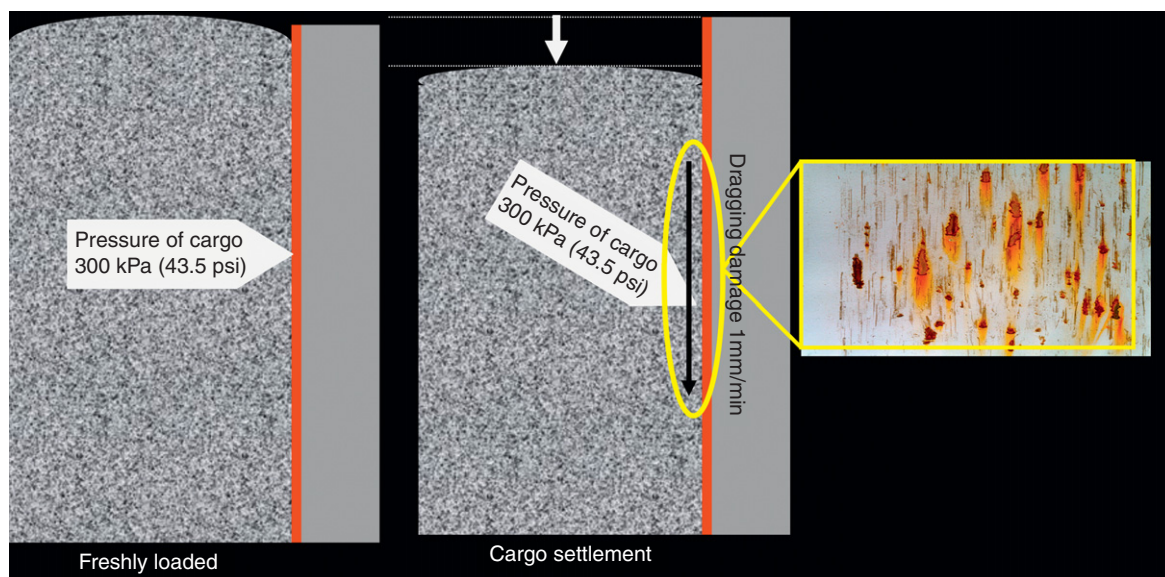

In addition to meeting the demanding performance requirements of the chemical and product tanker markets, the coatings should also be compliant with the appropriate regulations relating to the carriage of foodstuffs in contact with coatings. If the coating is not appropriately certified, it cannot carry certain cargoes.

Chemical tank coatings typically have to be replaced every 5–7 years. At Major Refurbishment, the tank is fully blasted to an Sa2½ standard and the coating system reapplied.

#### 4.14.4.5 Cargo Holds

Bulk carrier vessels transport dry cargoes, primarily coal, iron ore, grains, and bauxite/alumina. In 2007, ~1800 million tones of cargo was transported worldwide and the market is growing at typically 4–5% per annum fuelled by the rapid industrial growth in China and other Far East countries. The coatings applied in cargo holds have to resist the mechanical damage caused by the hard angular cargoes and the conditions experienced during cargo loading and unloading and while the vessel is at sea. The holds are normally loaded by dropping the cargo, using a conveyor or mechanical grab, from above the deck height (typically 30 m from the deck to the bottom of the cargo hold), while unloading is by mechanical grab. These processes have the potential to produce significant impact damage of the coating, particularly on the coated shedder plates and hopper sides at the bottom of the hold. Further damage of the coating can be caused by the slow settlement of the cargo during transportation; this produces a gouging action on the coating applied to the vertical walls of the hold,<sup>38</sup> and to minimize the damage the coating should have excellent abrasion resistance. An example of settlement damage of coatings is shown in [Figure 8](#).

Where coating damage occurs and the mild steel substrate is exposed, rapid corrosion will occur, particularly as (1) certain cargoes, such as coal, contain

**Figure 8** Settlement damage in a cargo hold.

**Table 7** Coating systems for cargo holds

Coating type	Typical specification (dft)		
Abrasion resistant epoxy	2×150 μm	↑ Increasing performance	↑ Increasing cost
Pure epoxy	2×150 μm		
Modified epoxy	2×125 μm		
Alkyd	2×75 μm		

impurities that accelerate the corrosion process and (2) several of the cargo holds will be fully or partially ballasted during the normal operation of the vessel.

For the carriage of grain, the impact and abrasion issues are greatly reduced; however, any coating, which is in contact with grain, should comply with the appropriate food contact regulations, for example, should be FDA certified.

The different types of coatings used in the cargo hold market are summarized in [Table 7](#). At New-building or Major Refurbishment, the coatings are applied by airless spray.

Although high volumes of one-pack alkyd products are used, it is recognized that the coatings offer only limited damage resistance, and extensive, frequent, repair of the coating will be required if coal or iron ore are carried in the hold. The alkyd coatings are, however, FDA certified and therefore represent a cost-effective coating system for vessels that specialize in grain carriage. Two-pack pure and modified epoxy-amine coatings provide improved damage resistance

and also have good intrinsic anticorrosive performance; the coatings are the same as those specified for use in ballast tanks and on the underwater hull. Hydrocarbon modification of the epoxy coating can have a detrimental effect on the damage resistance, while the aluminum pigmented pure epoxy-amine coatings are particularly resistant to gouging damage. The abrasion resistant epoxy-amine coatings contain a high loading of 'hard' pigments, such as bauxite and amorphous silica, and the polymer network is designed to provide excellent mechanical properties.

The coatings should develop good damage resistance shortly after application, including under the poor ventilation and low-temperature conditions frequently experienced in the bottom of the hold. Otherwise, high levels of coating damage may occur on loading and carriage of the first cargo. Avoiding over application of the coating and minimizing solvent retention are also important requirements.<sup>39</sup>

Epoxy-amine coatings provide effective damage resistance by transferring the impact energy through

to the steel substrate. An alternative approach is to use a highly elastomeric coating, which absorbs the impact energy. High-build, solvent-free, polyurethane elastomer coatings are used, albeit to a limited extent in comparison with epoxy-amine coatings, to protect the shedder plates and hopper sides, which are subject to the high levels of impact damage. Polymer sheet linings, based on high-density polyethylene, can also be used to protect specific areas in the cargo hold; these lining materials have found applications on certain specialist self-unloaded vessels.

The in-service lifetime of the cargo hold coating will depend on the coating type, the cargos carried, and the amount of OBM of the coating carried out by the crew. Typical lifetimes are modified epoxy 3–5 years, pure epoxy 5–7 years, abrasion resistant epoxy 10–12 years.<sup>38</sup> At Major Refurbishment, the entire cargo hold will be reblasted to an Sa2 standard and the coating system reapplied. As previously discussed, a large amount of OBM can be carried out in cargo holds, for both the alkyd and epoxy-amine coatings types. The same coatings applied at Newbuilding and Major Refurbishment can be used for OBM; however, a range of more surface-tolerant epoxy coatings are also used.

A current trend in the bulk carrier market is an increase in the vessel cargo loading speeds used in certain countries. Loading rates of between 3000 and 17 000 tones per hour are being achieved. The new high-speed conveyor and loading systems can, depending upon the procedure adopted, fire the cargo at high speed against the coated walls of the hold, leading to increased damage of the coating on the forward and aft bulkheads. It is currently unclear whether the current high-performance hold coatings will provide effective long-term protection for vessels using the new high-speed loading procedures.

#### 4.14.4.6 Other Vessel Areas

The preceding sections have focused on coatings for the vessel load carrying areas (cargo holds, cargo tanks, and chemical tanks) and the underwater hull and ballast tanks, which are critical areas with regard to fouling control and corrosion protection. There are a number of other areas on the vessel that also require coating: decks, topsides and superstructure, and internals. In general, the corrosion protection challenge in these areas is lower, reflecting the fact that the coated structure is not subject to permanent or periodic seawater immersion, or in extended contact with potentially damaging liquid or dry cargos. However,

exposure to a marine atmosphere is one of the most aggressive nonimmersion corrosive environments and the coating system can also be subject to UV degradation, which may lead to both a loss of aesthetic appearance and cracking of the coating. If cracking occurs, it may reduce the corrosion protection provided.

A wide range of coatings, both anticorrosive primers and cosmetic finishes, are applied on these vessel areas and the coating scheme selected is often determined by a combination of (1) the conditions that the coating will experience, (2) the required in-service lifetime of the coating, and (3) the ship owner's coating preferences, including potential cost restrictions.

##### 4.14.4.6.1 External decks

Coating systems for decks are required to provide damage and chemical resistance, cosmetic appearance, as well as effective corrosion protection. Representative coating schemes are indicated in [Table 8](#).

Increasingly stringent solvent emission legislation has resulted in a phasing out or a significant reduction in sales volumes of the low solids chlororubber-based coatings and thermoplastic acrylic finishes, which were previously widely used in the marine market. High volumes of the relatively low-cost alkyd coatings are used on decks, including zinc phosphate pigmented primers; however, there is an increasing trend toward specifying higher-performance epoxy primer systems. The epoxy primers are of the pure and modified epoxy type discussed in [Section 4.14.4.2](#). In general, the epoxy primers do not contain corrosion inhibitor pigmentation.

Significant differences are observed in the UV stability and durability of the different cosmetic finishes. Epoxy finishes undergo rapid UV degradation and chalking of the coating will be observed, while the more expensive polyurethane finishes

**Table 8** Typical coating schemes for external decks

Coating system	Scheme (dft)
Alkyd primer + alkyd finish	2×75 µm primer + 40 µm finish
Epoxy primer + epoxy finish	2×125 µm primer + 50 µm finish
Zinc silicate + epoxy primer + epoxy finish	75 µm zinc silicate + 75 or 150 µm epoxy primer + 50 µm finish
Epoxy primer + polyurethane finish	2×125 µm primer + 50 µm finish
Epoxy primer finish	2×150 µm
Epoxy primer + one-pack thermoplastic acrylic finish	2×125 µm primer + 40 µm finish

have excellent long-term stability. Alkyd finishes also exhibit good durability, but can be prone to yellowing on long-term exposure.

If required, nonskid characteristics can be introduced into the deck coating by the addition of aggregate pigmentation, either present in the liquid coating or applied onto the wet coating, immediately following spray application.

At Newbuilding and Major Refurbishment, coatings will be applied by airless spray, while for OBM, which will regularly be carried out by the crew, roller and brush application is widely used.

#### 4.14.4.6.2 Topsides and superstructure

The key performance requirements for the coating scheme are effective corrosion protection and good aesthetic appearance. As shown in Table 9, the typical coating schemes are similar to the schemes applied on decks.

Polysiloxane finishes, which provide excellent long-term durability, are being increasingly specified on vessels such as cruise liners where the aesthetic appearance is particularly important. The cost of the polysiloxane coating is higher than the other finishes used in the marine market.

#### 4.14.4.6.3 Vessel interiors

The main coating requirement is cosmetic appearance. Low-cost, fast drying, alkyd primers often containing zinc phosphate anticorrosive pigmentation are normally applied typically at  $1 \times 75 \mu\text{m}$  dft. The primer will either be topcoated with  $40 \mu\text{m}$  of an alkyd finish or wood veneers are attached over the primer. Waterborne one-pack acrylic primers and finishes have recently been introduced for use on vessel interiors. Although generally costlier than the alkyd system, the waterborne system provides significantly reduced solvent emissions.

**Table 9** Typical coating schemes for topsides and superstructures

Coating system	Scheme
Epoxy primer + polysiloxane finish	$2 \times 100 \mu\text{m}$ primer + $100 \mu\text{m}$ finish
Epoxy primer + polyurethane finish	$2 \times 125$ or $2 \times 150 \mu\text{m}$ primer + $1 \times 50$ or $2 \times 50 \mu\text{m}$ finish
Epoxy primer + epoxy finish	$1 \times 150 \mu\text{m}$ primer + $2 \times 50 \mu\text{m}$ finish
Alkyd primer + alkyd finish	$2 \times 75 \mu\text{m}$ primer + $40 \mu\text{m}$ finish

For interior areas, such as the floor in the engine room, which may be exposed to more aggressive conditions, epoxy-based coatings will be specified.

A number of specialist coating systems have also been developed for use on decks, topsides, and the vessel superstructure:

- Low solar absorption (LSA) coatings, which are designed to reduce the amount of near-infrared radiation absorbed by the coating, thereby reducing the coating temperature. LSA coatings are widely used on military vessels where it is important to control the temperature of the electronic defense systems in the vessel interior. Use of LSA coatings can also reduce the air conditioning requirements on other vessel types. LSA is primarily achieved through the careful selection of the pigments used in the coating.<sup>40</sup>
- Finish coatings that reduce the level of rust staining on the topsides and superstructure, a major issue on cruise liners and other vessels. The coatings contain a chelating agent, which coordinates with the ferrous ions to produce a colorless product.
- Deck coatings for military ships, which are designed to resist the short duration high temperatures associated with vertical take-off aircraft.

### 4.14.5 Future Trends

Obtaining effective long-term corrosion protection in the marine industry represents a major challenge. High-performance coating systems have been developed, which provide both long-term protection, thereby reducing coating maintenance costs and meet the other requirements of the shipyards and ship owners – coatings compatible with shipbuilding processes, minimize the application time and costs, compliance with environmental regulations, etc.

The last 20 years have seen major changes in the marine industry, which have resulted in significant changes to the type of coating systems used to protect ships. Continued change in the ship construction processes, ship operational procedures, and environmental and industry regulations are envisaged and will require further development of the coating systems used in the marine market. Future trends may include:

- Further reduction in permissible solvent emissions driven by environmental legislation. Increased use of high-solids, solvent-free, and waterborne coating systems can be anticipated. It is important to

recognize that, at present, waterborne coatings are not widely used in the marine market. This reflects (1) the temperature and humidity restrictions on the use of this type of product, (2) the higher cost, depending upon coating type, and (3) concerns over the anticorrosive performance and osmotic blistering susceptibility of waterborne epoxy anticorrosive coatings if used on areas subject to permanent or periodic immersion.

- Increasing health and safety concerns over certain materials used in marine coatings, for example, low molecular weight epoxy resins, amine curing agents, biocides, and isocyanates.
- A requirement for increased coating lifetimes in key vessel areas such as ballast tanks and cargo holds.
- Changes in the design of ships. The use of composite materials as a replacement for steel<sup>41</sup> and the use of steel-laminate-steel structural laminates<sup>42</sup> have recently been proposed. Aluminum is being increasingly used in the fast ferry market.
- Changes to the ship construction and Newbuilding coating processes. The use of higher-speed and alternative welding and cutting techniques, for example, laser welding.<sup>43</sup> The potential use of robotic coating application as a route to reduce application costs and improve the coating thickness control. Development of ultra fast drying anticorrosive coatings, which significantly reduce the time required to paint the blocks, which can be a major bottleneck in the ship construction process. For this last opportunity both modified epoxy and polyurea/polyurethane coatings are currently being investigated.<sup>44,45</sup>

### Glossary

**Bell hole** Area of ground excavation around a pipeline that allows inspection and/or repair work to be carried out on the pipeline in a selective location.

**Cup shot** A sample of a liquid coating taken during the coating application usually in a plastic cup or similar receptacle. Once the liquid coating has fully cured, tests can be carried out to verify that the coating components have been mixed in the correct proportions.

**Cut back** When line pipe is coated, a small area at each end of the pipe is left free of protective coating so that adjacent sections of pipe can be welded together without the heat from the welding damaging the coating. The area of the joint (the field joint) is prepared and coated after welding.

**Fusion-bonded epoxy (FBE) powder** A protective coating supplied in powder form, containing both a base resin and a curing agent. The powder is stable at room temperature. When the powder is heated to within a certain temperature range, the powder melts and a chemical reaction takes place between the two components, which results in a complex stable polymer film.

**Intelligent pig** An electromechanical device which travels inside a pipeline measuring the pipe wall thickness.

**LPG** Liquid petroleum gas, that is, either liquefied butane or liquefied propane.

**Off ratio** Two-component coatings like epoxies and polyurethanes require the two components to be mixed in the

correct ratio to achieve optimum performance from the finished coating. The correct mixing ratio is prescribed by the coating manufacturer with an appropriate tolerance. If the actual mixing ratio is outside of the prescribed tolerance, that is, off ratio, then the optimum coating performance will not be achieved.

**Pot life** Protective coatings such as epoxies and polyurethanes are supplied to the applicator in two parts: a base and a curing agent. The two parts must be thoroughly mixed together before application in order for their corrosion protection qualities to be fully realized. Once the coating has been thoroughly mixed, the applicator has a finite time in which to apply it. This is known as the pot life. For many solvent-containing epoxies and polyurethanes, the pot life will be of the order of 1–2 h. For solvent free formulations, the pot life may be as short as 1–2 min, depending on the application temperature. If the coating is applied outside of the pot life, its protective qualities may be severely compromised.

**Tenting** Where discontinuities occur in the surface of a structure, for example at weldments, certain semirigid coating types, in particular cold-applied tapes, experience difficulty in conforming to the discontinuity. Instead, the discontinuity is bridged and a tent is formed at the location providing a weakness in the corrosion protection.

## Abbreviations

**HDPE** High density polyethylene

### 4.15.1 Introduction

The most important types of steel structures affected by corrosion because of contact with the ground are: buried transmission pipelines and buried process piping networks, structural support piles, well casings, and above- and belowground storage tanks. A detailed discussion of the protective coatings applied to these structures is considered to be the best means of

describing coatings for corrosion protection where steel is in contact with the ground.

The corrosivity of soil is determined by many factors, the principal ones being

- the soil type (sand, clay, chalk, carbonaceous, etc.)
- the degree of compaction,
- the water content and salinity,
- the oxygen content, and
- the extent and the prevalence of sulfate-reducing bacteria.

For buried steel structures, maintenance may be difficult or even impossible, and it is usually necessary to provide some form of corrosion protection in order for the structure to meet its design life. The corrosion protection will normally involve a protective coating often supplemented by cathodic protection. Protective coatings used on buried structures act as physical barriers, which isolate the structure from the surrounding environment. They must be sufficiently robust to withstand construction activities, including transportation to site, handling, and burial, and can vary in thickness from 500  $\mu\text{m}$  to several millimeters. In service, the cathodic protection prevents corrosion from occurring at holidays in the coating, which result mainly from mechanical damage.

Improvements are continually being made to the quality of protective coating materials and to their methods of application. Nevertheless, it is virtually impossible to produce a protective coating that will protect 100% of the surface of a buried structure for the full design life at an economic cost. This is largely due to the skills required to apply these coatings successfully and the many opportunities, which exist for the coating to become damaged. The coating may suffer handling damage, during transportation to site and during construction. It may be penetrated by rocks during backfilling and by ground settlement following construction. Air–soil interfaces on partially buried items can be particularly vulnerable to mechanical damage. Some pipe coatings have been known to split because of the stressing of the coating in-service as a result of the repeated cycle of wetting and drying of the surrounding soil. All of these events inevitably result in isolated areas of bare metal being exposed to the possibility of soil corrosion. In the majority of cases, the combination of a protective coating with cathodic protection offers the best economic solution to soil corrosion. Therefore, protective coatings used on buried structures need to be compatible with cathodic protection.

Protective coatings used on buried structures may be divided into several generic types, namely

- liquid coatings (paint) applied manually by brush, by airless or conventional spraying, by roller, or by dipping;
- tape wrappings applied by hand or by wrapping machine;
- radiation cross-linked heat-shrinkable materials;
- reinforced coal tar or asphalt enamel coatings, applied in the factory or at site;
- fused (mostly epoxy) powder coatings applied by flock spray or fluidized bed, mainly under factory conditions; and
- multilayer coatings comprising a polyolefin outer layer applied on top of an adhesive with or without a fusion bonded epoxy (FBE) powder coating applied as a first coat. These are factory-applied coatings and their use is confined to pipelines.

The selection of the type of coating will be strongly influenced by the size and geometry of the item, the method of construction, and the operating conditions. For multiple items of the same geometry, such as sections of straight line pipe, factory application of the coating to individual pipe lengths on a continuous production line represents the most economical method of applying a protective coating. Numerous coatings have been developed, which lend themselves to this type of application, and will be dealt with in more detail later.

For single, large, or complex geometry items, such as storage tanks, buried piping networks at process sites, valves, etc., liquid coatings applied by spray, brush, or dipping (where size allows) represent the most practical solution.

For some applications, such as pipelines through marshland, or coastal inlets, the protective coating may be supplemented with an outer concrete compression coating to provide additional mechanical protection and negative buoyancy.<sup>1</sup>

For all coating types and methods of application, quality control at every stage is crucial to the long-term performance of the selected coating. The quality of surface preparation is arguably the single most important factor, which determines the lifespan of the coating (see [Section 4.15.3](#)). More will also be said about quality control in [Section 4.15.7](#).

#### **4.15.2 Properties Required of Coatings for Steel in Contact with Soil**

The purpose of applying a coating to a buried structure is to prevent direct contact with the surrounding

soil over the lifetime of the structure. With this requirement in mind, the characteristics required of a protective coating for buried steel are as follows:

1. *Ease of application:* It must be possible to apply the coating in the factory, the coating yard, or in the field at an economical rate, using the standard tools and equipment that are available.
2. *Resistance to handling damage:* It must be possible for the structural item to be handled reasonably quickly after the coating has been applied without damaging the coating. For liquid-applied materials, this means a short drying time.
3. *Good adhesion to the metal surface:* The coating must have an excellent bond to steel. To this end, some coating systems include specific primers to promote superior adhesion of the complete system to the substrate.
4. *Resistance to impact:* The coating must be able to withstand reasonable levels of impact without cracking, chipping, or disbondment.
5. *Resistance to abrasion:* Where relative movement between the coated item and the ground, or other structures is inevitable during construction, then the coating must have good abrasion resistance. This is particularly important in the case of driven piles and water or hydrocarbon well casings.
6. *Flexibility:* The coating must be flexible enough to withstand such deformation as may occur during construction, for example, during field bending or laying of pipe and during the lifting and placement of buried storage tanks, etc. The coating must also accommodate any expansion or contraction that may occur because of significant changes in environmental or operating temperatures.
7. *Resistance to soil stress:* Coatings on buried structures are often subject to very high shear stresses, due, for instance, to the contraction of clay soils during periods of very dry weather. The coating must be able to resist such stresses without suffering damage.
8. *Water resistance:* The coating should display a low rate of water absorption and be resistant to water or water-vapor transmission through it.
9. *High electrical resistance:* The coating must be an electrical insulator free of any significant amounts of electrically conductive material.
10. *Chemical and physical stability:* The physical properties of the coating must remain stable, showing negligible change under the prevailing operating conditions.

11. *Resistance to bacteria:* The coating must be resistant to the action of destructive effect of any bacteria in the soil.
12. *Resistance to marine organisms:* For structures buried in coastal areas, the coating should be resistant to penetration by marine organisms.
13. *Resistance to cathodic disbondment:* Where the coating is to be used in conjunction with cathodic protection, it must be resistant to the high levels of pH, which are generated at coating breaks, as the protective current flows to the exposed steel surface.

### 4.15.3 Preparation of Metal Surfaces

The single most important factor determining the lifespan of a protective coating is the quality of the surface preparation. Before applying a protective coating, it is essential to ensure that the surface is free from rust, mill scale, moisture, loose dust, grease, or any other form of surface contamination. The best time for achieving the optimum standard of surface preparation is when the item is new. Once significant corrosion has taken place, it is far more difficult to achieve the high standard of surface preparation required for coating longevity.

The first stage in the preparation process should be the complete removal of all dirt and grease using either a proprietary detergent–water solution followed by freshwater, or an organic solvent.<sup>2</sup> Once all grease and dirt have been removed, a number of surface preparation methods may be used to remove rust, mill scale, and old coatings as follows:

1. *Mechanical cleaning:* This includes the use of wire brushes or abrasive paper either handheld or mounted on rotary power tools, and scrapers, and needle guns. Although scrapers, wire brushes, and abrasive paper are able to remove loose rust and scale, they do not remove more adherent layers and tend to polish the steel surface. Protective coatings adhere best to surfaces that are contaminant-free and not smooth. They need to have a surface profile or anchor pattern in addition to being clean. Needle guns are more effective at removing tightly adherent rust and scale, but progress is slow and this form of surface preparation is impracticable for anything other than small areas.
2. *Dry abrasive blast cleaning:* The projection of small particles of hard nonmetallic particles, or steel shot or steel grit at metal surfaces, using compressed air or centrifugal wheels is an extremely efficient form of removing all rust, mill scale, and old coatings. Abrasive blasting is capable of leaving a very clean steel surface and a surface profile, which optimizes coating adhesion. The cost of attaining a very high standard of cleanliness is considerable, and careful consideration should always be given to specifying the correct level of abrasive blasting for the particular application.<sup>3</sup>
3. *Pickling:* Dipping in inhibited hydrochloric or sulfuric acid is a commonly used factory method of removing mill scale from steel, particularly in conjunction with hot phosphoric acid dipping (the Footner process). It is mainly used in the steel manufacturing industry and for the pretreatment of steel prior to the application of specialized coatings such as hot dip galvanizing and electrodeposits. It is rarely used as a method of surface preparation before the application of the types of protective coatings used on buried structures. Published specifications are available covering the pickling process.<sup>4</sup>

Before the application of any coating, the quality of the prepared surface should meet specific inspection requirements with regard to the visual appearance,<sup>2</sup> the degree of dust contamination,<sup>5</sup> and the surface profile.<sup>6</sup>

Both before and during surface preparation and coating application, it is necessary to ensure that condensation is not likely to occur to the detriment of the final protective coating quality.<sup>7</sup> Regardless of which method of cleaning is adopted, it is important to apply the first coating layer as soon as possible after the cleaning operation and before any deterioration in the prepared surface.

### 4.15.4 Specific Coating Material Types and Their Applicability

#### 4.15.4.1 Liquid-Applied Coatings (Paint)

The earliest coating types used on buried steel were based upon coal tar or bitumen often blended with a volatile solvent. In the absence of the solvent, the coating material had to be heated until molten and then poured onto the steel surface or the item had to be coated by being dipped into a hot bath of the liquid coating. When blended with a volatile solvent, the coating could be applied at room temperature and dried by evaporation of the solvent, to leave a

protective film on the steel surface. The solvent-blended coatings could be applied very simply by brush, or for smaller compact items, by dipping. Regardless of the coating type and the application method, the coatings were brittle and prone to mechanical damage. Significant improvements in mechanical properties were made by the addition of fillers, and in the case of coal tar coatings for pipelines, the inclusion of fabric reinforcement. More will be said about reinforced enamel pipeline coatings later.

Today, the most commonly used liquid-applied coatings for buried steel are based on two-component epoxy or polyurethane formulations.<sup>8,9</sup> Both types require thorough mixing of their two components before application. A chemical reaction takes place resulting in cross-linking of the molecules of the base resin by molecules of the curing agent. The fully cured coatings adhere rigidly to well prepared steel and are very resistant to mechanical damage. Until recently, epoxy and polyurethane formulations containing coal tar were very popular for protecting buried steel, such types having built up a strong reputation of long-term performance over many years because of the improved chemical resistance that coal tar imparts at reduced cost. However, health and safety concerns over the carcinogenic nature of the polycyclic aromatic compounds contained within coal tar and released during heating have led to a significant decrease in the availability of epoxy and polyurethane formulations containing this material in recent times.

Additional health and safety concerns over solvent emissions and the demand from customers for rapid curing have led to significant developments in epoxy and polyurethane coating technology. Solvent-free formulations now exist that satisfy health and safety legislation but require an enhanced degree of sophistication during application, due mainly to the short pot life of the mixed constituents. The principle method of application is by airless spray without any premixing of the two components. Instead, the two components are pumped separately to a mixing chamber just ahead of the spray gun to ensure that the short pot life of the fully mixed coating is accommodated. The curing rate can be further enhanced by thermostatically controlled heating of each separate component prior to mixing, with the final application temperatures being as high as 80°C for some formulations. As a result, the coatings fully cure in a matter of hours, which is a major advantage for the applicator, as coated items can be handled a few hours after coating compared with several days for the solvent-based alternatives. The principal use of epoxy and polyurethane coatings is in the protection from soil corrosion of buried tanks and associated piping, and pipeline components such as thrust bore sections, field joints, preformed pipe bends, and valves. **Figure 1** shows several LPG storage tanks coated with a solvent-free coal tar polyurethane prior to encapsulation in a burial mound.

Liquid-applied epoxies and polyurethanes have also found use on above-ground storage tanks, specifically

**Figure 1** Large LPG storage tanks externally coated with a solvent-free coal tar urethane awaiting burial.

on the undersides of the floor plates where the steel is in intimate contact with the tank mound. This is to help reduce the risk of under-floor corrosion, which can lead to perforation of the floor plates and the loss of product containment. Complete coverage of the undersides of the floor is not possible because of the method of construction. The plates can be coated prior to laying down the floor, but the edges have to be left bare to accommodate welding. Once welded in place, the undersides of the weldments are not accessible and have to be left bare. Nevertheless, the practice of painting the undersides of the plates before laying down the floor significantly reduces the area of bare metal in contact with the foundation mound and enhances the spread of protection from the cathodic protection system.

#### **4.15.4.2 Cold-Applied Tapes**

##### **4.15.4.2.1 Petrolatum tapes**

Petrolatum has, like lanolin, long been recognized as possessing corrosion preventative properties. Petrolatum tapes consist of a synthetic fabric carrier impregnated with petrolatum. Modern petrolatum formulations incorporate biocides to inhibit bacterial growth. The tapes are applied by hand over a soft petrolatum-based paste primer and are sufficiently conformable to accommodate irregular surfaces, such as flanges, large bolts, etc. They do tend to remain sticky to the touch long after application.

##### **4.15.4.2.2 Pressure-sensitive tapes**

Unlike petrolatum tapes, which possess corrosion-inhibitive properties, pressure-sensitive tapes rely entirely upon the prevention of the ingress of moisture to the metal surface to prevent corrosion. The tapes usually comprise a polyethylene or polyvinylchloride film of 0.25–0.5 mm thickness, with the inner surface coated with a thin layer of adhesive, often rubber-based. The adhesive is usually between 25 and 100- $\mu$ m thick. They have minimal conformability and therefore cannot be used to wrap complex shapes. In addition, their resistance to mechanical damage and adhesion to steel are also limited. These tapes resemble those commonly used by electricians to bind electrical wiring and have limited use in corrosion protection applications other than as a temporary solution to a minor problem.

##### **4.15.4.2.3 Laminated tapes**

In a more general use as protective coatings for buried pipework are tape wrappings comprising a

polyvinyl chloride or polyethylene carrier with a minimum thickness of 0.75 mm and an inner layer of a self-adhesive bituminous rubber compound with a minimum thickness of 0.8 mm.<sup>10</sup> These tape coating systems include a quick-drying primer with good adhesion to both the bituminous rubber compound and the prepared steel substrate. As with pressure sensitive tapes, laminated tapes have limited conformability and their use is mostly restricted to uniform cylindrical shapes such as buried pipe work. Laminated tapes are usually applied by hand or wrapping machine as a 55% minimum overlapping spiral, starting and ending with a double wrap and a neat square end. The application is easier and the performance is likely to be superior on smaller diameter pipe (<250 mm, say). During the application, care has to be taken to avoid tenting at weld seams, and where the weld cap is prominent, this may require the use of weld seam cover tape or proprietary mastic filler. Tenting may result in water channeling beneath the coating and localized corrosion of the substrate.

Laminated tape components are thermoplastic and the tapes have limited environmental and operating temperature resistance. Allowing tape-wrapped items to sit out in the hot sun prior to burial can result in distortion, disbondment, and blistering of the tape. Service at elevated temperatures may result in the movement of the tape wrapping relative to the coated item, exposing the substrate to soil corrosion.

#### **4.15.4.3 Line Pipe Coatings**

##### **4.15.4.3.1 General**

In the oil and gas industry, transmission pipelines are almost always of an all-welded construction. At the pipe mill, the pipe is manufactured in fixed lengths, usually 12 m, and is supplied to the pipeline construction site already factory coated to within several inches of the pipe ends. The coating cut-back is provided at each end in order to minimize damage to the coating from the heat generated during field welding operations. Once the field weld has been completed and inspected, the bare steel at the weld area and at the adjacent cut-back is cleaned and prepared (see [Section 4.15.3](#)), and a field joint coating is applied. The first 50–75 mm of the factory-applied coating is also prepared and the field joint coating overlapped onto it. Clearly, the factory coating and the line pipe coating have to be compatible and of a similar durability.

At the pipeline design stage, it is customary for the selection of an economic pipe wall thickness to be dominated by pressure containment considerations and any corrosion allowance is normally limited to a few millimeters at most. Thus, the integrity of the protective coating is paramount in ensuring the long-term integrity of the pipeline.

**Figure 2** shows a schematic of the typical layout of a line pipe coating factory. The manufactured pipe enters the coating factory via the incoming pipe racks, and all dirt and grease are removed as the pipe passes through the washing unit. The pipe is then heated to typically 40–80 °C to drive off any residual moisture and ensure that the pipe temperature is maintained above the dew point throughout the ensuing surface preparation stage. The warm pipe enters an enclosed wheelabrator cabinet, where a mixture of steel shot and grit from a vertical hopper is propelled at high velocity on to the pipe surface via bladed wheels rotating at very high speeds. The steel shot, impacting on the surface with great force, breaks up the surface mill scale. The steel grit produces an angular surface profile on the pipe surface, which is necessary for optimum coating adhesion. After emerging from the cabinet, any surface debris, such as dust, spent grit, etc., is removed by vacuuming or brushing with stiff bristle brushes or a combination of the two.

Debris is normally removed from the inside of each pipe by air blowing (not shown). Inspection racks are normally provided to permit inspection of the surface preparation quality before coating application.

Following the inspection and acceptance of the prepared surface, the pipe is transferred from the inspection racks onto a second conveyor system where a surface chemical pretreatment may be applied before further preheating and coating application. If chemical pretreatment is used, it usually involves the application of either a phosphate or chromate solution, sometimes, both in succession. The chemicals used are proprietary, being individually formulated for use with specific coating systems in line pipe coating plants.<sup>11</sup>

The specific example shown in **Figure 2** involves the application of a three layer FBE–polyethylene coating, but the basic layout is typical of most modern line pipe coating factories. In the example shown in the figure, the prepared pipe is induction heated to the required temperature before the FBE powder is applied by electrostatic air spray. A polyethylene adhesive is then side extruded on to the FBE coating, followed by the side extrusion of the polyethylene outer coating.

The completed coating is cold water quenched to enable the coated pipe to be handled safely and

**Figure 2** Schematic of a modern line pipe coating plant.

moved without damaging the coating. More will be said about this line pipe coating system later.

#### **4.15.4.3.2 Coal tar and asphalt/bitumen enamels**

Coal tar and bitumen were first used to protect pipelines from external corrosion in the 1870s. However, until the end of nineteenth century, these materials were not satisfactory as pipeline coatings, being, for the most part, brittle at low temperatures and soft and sticky at higher temperatures. Progressive developments included the incorporation of pulverized coal in coal tars and mineral fillers in both coal tar and asphalt coatings. These increased-viscosity formulations gave thicker films, but poorer wetting of the steel surface and necessitated the introduction of low-viscosity priming coats. The incorporation of reinforced glass inner wraps and asbestos felts, then to be replaced by the more modern glass fiber outer wraps, resulted in a much increased coating strength, and correspondingly, an enhanced protection against impact and soil stressing. Throughout all of the early developments, the importance of surface preparation on coating performance appears to have received little attention, the removal of oil and grease from the steel surface being the only major concern. Despite this apparent absence of rigorous substrate preparation, there are reports of coal tar enamel coatings on pipelines still being in good condition after more than 70 years in service. The early coatings were invariably applied on site using 'over the ditch methods' comprising various forms of line traveling equipment.

Only with the introduction of the more modern coatings, such as fusion bonded epoxies, in the early 1960s (see later), did the importance of good surface preparation and application under factory conditions to the consistency of asphalt or coal tar enamel coating performance become fully appreciated.

Hot-applied asphalt and coal tar coatings with their priming systems are now well classified, described, and specified in BS 4164:1967 (coal tar)<sup>12</sup> and BS 4147:1967 (bitumen),<sup>13</sup> but no guidance is given in these standards on the application procedure. The procedure commences with the application of a thin-film primer to the prepared pipe surface usually by spraying. Once the primer is dry, the hot molten enamel (200–240°C) is poured over the rotating pipe. The hot enamel layer is immediately over wrapped with a continuous spiral of fibre glass inner reinforcement tape applied under just-sufficient tension to imbed the outer half of the still molten

enamel layer. A second wrap or outer wrap of glass fiber preimpregnated with enamel is subsequently applied to produce a coating of 5 mm minimum thickness.<sup>14,15</sup>

Asphalt enamel coatings are generally regarded as inferior to coal tar enamel coatings because of their higher rate of water uptake and poorer mechanical strength, and this has resulted in the decline of the popularity of asphalt enamels in favor of coal tar over the past 30 years. Coal tar contains polycyclic aromatics, which are known carcinogens, and this has led to at least one major protective coating manufacturer's removing coal tar completely from their protective coating formulations. For these reasons, the use of asphalt and coal tar enamel coatings on buried pipelines has largely been superseded by more modern alternatives described in the following sections.

#### **4.15.4.3.3 FBE powder coatings**

Fusion-bonded epoxy (FBE) powder, thermosetting resin, thin-film coatings were first used as stand-alone coatings on pipelines in the early 1960s. FBEs cure by chemical reaction of a curing agent with a base resin analogous to liquid epoxies, except that elevated temperatures (180–240°C) are required for the chemical reaction to take place. Early formulations had poor flexibility and coated pipes could not be field bent. Over the next 20 years, developments in resin and curing agent formulations resulted in FBE coatings with improved flexibility without significant compromises in hot water and cathodic disbondment resistance.<sup>16</sup> Today, it is claimed that, there are in excess of 100 000 km of FBE-coated pipe installed throughout the world, mostly belowground. Originally developed as a single-coat system, typically 350–600-μm thick, more recent developments have included thicker dual-coating layer combinations. The main advantage of the dual-layer systems has been that they either increase the resistance to mechanical damage during transport and construction or improve the performance at high pipeline operating temperatures (>90°C). As mentioned previously (see introduction to this section and [Figure 2](#)), FBE coatings have also become established as the primer layer in three-layer polyolefin coatings. A first layer of FBE enables polyolefin coating adhesion strengths of steel to be achieved, which are an order of magnitude higher than those possible without FBE. More will be said about polyolefin line pipe coating systems later.

One of the major advantages of FBE coatings is that they can be applied to line pipe, bends, fittings,

and field joints, enabling just one coating system to be specified for the entire pipeline. This eliminates problems associated with the selection of the coating at field joints where, otherwise, two generically different coatings may have been applied to the parent line pipe on either side of the field joint, presenting significant coating compatibility problems.

FBE coatings are less forgiving of substandard surface preparation than are the reinforced enamel coatings, and a satisfactory long-term FBE coating performance is reliant upon a rigid adherence to established surface preparation and coating application procedures regardless of whether the coating is applied in the factory or the field.

The FBE application process is as follows: once the pipe surface preparation is complete, including chemical treatment (where specified), and the standard is acceptable, the pipe is induction heated to a temperature usually in the range 210–240°C. The coating, which is in dry powder form, is electrostatically sprayed onto the rotating pipe using a number of low-pressure spray guns. The powder melts as it hits the hot pipe surface, thoroughly wetting the steel substrate. The axial and rotational speed of the pipe is carefully controlled to ensure that the correct coating thickness is applied using a set number of spray guns. Most FBE coating plants incorporate a reclaim system for collecting, cleaning, and recycling any surplus powder that has failed to make contact with the hot pipe. At such high substrate temperatures, the coating on the pipe cures within 1–2 min, and the coated pipe is immediately quenched, as it travels through a water cascade system. This allows the pipe to be handled and inspected very soon after the coating has been applied.

#### **4.15.4.3.4 Polyolefin coatings**

The early 1960s also saw the emergence of polyethylene as a commercial external pipeline coating system. Its inherent toughness was seen as the answer to the mechanical damage suffered by asphalt and coal tar enamel pipeline coatings, either during pipeline construction or in service. Poor or nonexistent grading of the pipeline trench backfill through rocky terrain can be particularly damaging for reinforced enamel coatings. The first polyethylene coatings were applied either as a powder by sintering or by hot extrusion as a film over a soft mastic adhesive. Neither of these application methods resulted in satisfactory adhesion of the coating to the steel substrate. In the case of the latter, the adhesive was brittle at temperatures close to 0°C, and its viscosity was drastically reduced above 50°C enabling the outer

polyethylene sleeve to move relative to the pipe. Furthermore, the early grades of polyethylene were difficult to extrude and the coatings would suffer shrink back from the pipe ends, following application. The differential expansion rates between polyethylene and steel could also result in the crimping of the field joint coating at the joints, and the early polyethylene films also suffered environmental stress, cracking in service. Improvements in the grade of polyethylene used plus the development of a hard ethylene copolymer adhesive gave better adhesion quality and a more robust coating. A two-layer polyethylene/rubberized asphalt adhesive external pipeline coating system (yellow jacket<sup>®</sup>) is still used in the United States and Australia.<sup>17</sup>

A major break through in the adhesive bonding of polyethylene to steel came in 1982 with the advent of the three-layer FBE–polyethylene pipeline coating system. The development of a polyethylene copolymer that could cross link with FBE during the gel stage of the epoxy application process enabled peel adhesion strengths between polyethylene and steel to be obtained of a magnitude, perhaps never envisaged before.<sup>18</sup> As the FBE powder hits the hot pipe, it melts and becomes gel-like for a finite time, which is governed by the applied FBE powder coating thickness and the pipe temperature. For a typical FBE powder, the gel time can vary from 5 to 60 s depending upon these variables. Hence, the speed of the pipe plus the proximity of the extruders to the FBE application chamber must be carefully adjusted to ensure contact between the FBE in gel form and the polyolefin copolymer, and cross-linking between the two. The application process for three-layer polyethylene is shown in [Figure 2](#). The application procedure for the FBE first layer is identical to that described earlier for standalone FBE coatings. The extrusion temperatures for the polyethylene adhesive and the polyethylene outer coating are normally in the ranges 190–210°C and 200–240°C, respectively. The FBE coating thickness is controlled by the number of electrostatic spray guns and the lateral and rotational speed of the pipe. For the polyethylene adhesive and top coat, the thickness is also governed by the speed of the pipe and also the width settings on the extruders. Typical specified individual layer thicknesses are FBE 75–350 µm, adhesive 400–600 µm, and top coat 1.5–2.5 mm.

The full coating system is cold water quenched to allow early handling and inspection.

An extension of this technology to polypropylene followed in 1989, and with it, the development, for

the first time, of a coating with the ability to perform satisfactorily at operating temperatures up to 125°C.<sup>19</sup> By comparison, the upper operating temperature limits for FBE–polyethylene coatings are normally in the range 70–80°C. The factory coating application process for three-layer polypropylene is almost identical to that for three-layer FBE–polyethylene shown in [Figure 2](#).

Three-layer coating systems combine the good adhesion of FBE to steel, with the enhanced mechanical and environmental degradation resistance of the modern thermoplastic polyolefins.

#### 4.15.4.4 Field Joint Coatings

##### 4.15.4.4.1 General

Before the advent of factory coating application to line pipe, asphalt and coal tar enamel coatings were applied on site over or adjacent to the pipeline trench. This meant that the field joints were not, in themselves, a specific concern, as the coating could be applied in a more or less continuous manner to long sections of welded pipe along the pipeline way before burial. It was only when these coating materials began to be applied to individual lengths of pipe under factory conditions that field joints became a subject of attention. At first, the field joints on coal tar and asphalt enamel factory-coated line pipe were coated in a manner analogous to the coating of the line pipe, that is, using hot enamel and fabric reinforcement applied as a full circumferential wrap. This archaic procedure has been largely superseded over the last 30 years by the application of cold-applied synthetic rubber adhesive backed PVC or polyethylene tapes (see [Section 4.15.4.2.3](#)), radiation cross-linked

heat shrink sleeves (see [Section 4.15.4.4.3](#)), or liquid-applied coal tar modified two-pack epoxies and polyurethanes (see [Section 4.15.4.4.2](#)).

Liquid epoxies and polyurethanes, cold-applied tapes, and radiation cross-linked shrink sleeves have all been used to coat the field joints on FBE and two- and three-layer polyethylene-coated line pipe in recent times.

Three-layer FBE–polypropylene coatings are usually selected for the line pipe coating where a high resistance to mechanical damage is required and the operating temperature exceeds that, which can be handled satisfactorily by any of the alternative line pipe coating systems available and previously described. Correspondingly, it is usual to specify an analogous FBE–polypropylene coating system for the field joints in order to ensure that the performance of the field joint coating approaches that of the line pipe coating.

Driven by a need to achieve consistent field joint coating quality at economic production rates, the pipeline coating industry has made significant technological developments in field joint coating procedures in the last 20 years. Modern application methods necessitate the use of induction coils and invertors, fluidized beds, thermostatically controlled heaters, automated spray, or wrapping equipment plus diesel generators to provide the necessary power. All of the equipment needed is containerized and the containers are mounted on lorries or caterpillar-tracked vehicles, see [Figure 3](#).

##### 4.15.4.4.2 Liquid-applied field joint coatings

The major developments in solvent-free two-pack liquid epoxy and polyurethane coating technology

**Figure 3** Typical field joint coating spread, including weatherproof shelters.

have already been mentioned in [Section 4.15.4.1](#). These materials are widely used as field joint coating materials and are regularly applied using automated spray equipment of the type shown in [Figure 4](#). The temperature of the separate components is thermostatically controlled inside furnished containers. The separate components travel to the spray head mounted on the carriage via a thermally insulated umbilical. A mixing chamber located just before the spray head ensures thorough mixing before application. A third process line in the umbilical allows the mixing chamber and spray head to be flushed with solvent to prevent them from becoming blocked between successive spray applications. During spraying, the spray head rotates around the pipe first in one direction and then in the other a sufficient number of times, depending upon the required coating thickness.

#### **4.15.4.4.3 Radiation cross-linked heat shrink sleeves**

The standard radiation cross-linked heat shrink sleeve comprises an expanded polyethylene backing with a heat-sensitive adhesive and is applied either over a steel surface primer or directly on to the field joint area. Heat is applied both before and after the application of the sleeve and care must be taken to ensure that the heating process does not damage the parent coating on either side of the field joint. Careful fitup and controlled uniform heating are essential to ensure uniform shrinkage and to avoid bubbling and blistering of the sleeve during the shrinking process. Although an open flame torch is the preferred method of both pre- and postheating

by most applicators, induction heating provides a superior method of ensuring a uniform heat distribution at the preheat stage.

As with cold-applied tape wrappings, the components of polyethylene heat shrink sleeves remain thermoplastic after application, and their service temperatures are therefore limited.

In addition to their use on asphalt and coal tar enamel factory-coated pipe, heat shrink sleeves have also been used at field joints on FBE and two- and three-layer polyethylene-coated line pipe.

Recent developments have included an expanded polypropylene version for use with three-layer FBE–polypropylene factory-coated line pipe at high service temperatures ( $>60^{\circ}\text{C}$ ). The application of this latter product requires a much higher heat input to the field joint area both before and following sleeve fitup but provides significantly improved levels of adhesion to both the pipe and the polypropylene factory coating at elevated service temperatures.

#### **4.15.4.4.4 FBE powder coatings**

Reference has already been made to the use of FBE as a field joint coating material for FBE-coated line pipe. The field application of FBE is similar, in most respects, to the factory application in that an induction coil is used to heat the field joint area to the required temperature ( $210\text{--}240^{\circ}\text{C}$ ) before the powder coating is applied by low pressure air spray. The process requires a substantial amount of portable equipment, including a hinged induction coil (see [Figure 5](#)) and inverter and a fluidized bed, from which the airborne powder is conveyed to the

**Figure 4** Application of a two-pack solvent-free liquid coating to field joints on large diameter pipe.

**Figure 5** An induction coil being lowered into place over a prepared field joint on a large diameter pipe.

application jig. The application equipment comprises a hinged cylindrical frame, which fits around the field joint area and contacts the pipe via a number of wheels (see [Figure 6](#)). The frame is motorized so that it can be rotated around the pipe, first in one direction and then the other. The FBE powder is sprayed onto the hot pipe from a low-pressure air spray head mounted on the frame as the frame rotates around the pipe.

#### 4.15.4.4.5 FBE–polypropylene

The introduction of the three-layer FBE–polyolefin coatings initially created a dilemma for field joint coating system specifiers as a few, if any, of the traditional field joint coating systems mentioned earlier adhere to polyolefin surfaces to a totally satisfactory degree, particularly at operating temperatures above  $\sim 40^{\circ}\text{C}$ . Correspondingly, the last 5–10 years have seen considerable development activity on behalf of the field joint coating specifiers and application contractors, to produce a field joint coating with the ability to match the performance of and be compatible with three-layer FBE–polypropylene line pipe coating.<sup>20</sup> As a result, six different field joint coating systems have been used. They may be summarized as follows:

1. Sintered polypropylene copolymer.
2. Coextruded polypropylene sheet.
3. Injection molded polypropylene.
4. Flame sprayed polypropylene copolymer.
5. Coextruded polypropylene tape.
6. Polypropylene heat shrink sleeve.

**Figure 6** A typical coating application frame used for the application of FBE powder coatings at field joints. Courtesy by Offshore Joint Services, Houston, TX.

With the exception of the polypropylene heat shrink sleeve, which is described earlier, all of these systems incorporate the application of FBE as the first coating layer in the manner described earlier. This is followed immediately by a sprayed layer of polypropylene copolymer adhesive powder usually from a second coating head mounted on the FBE coating frame (see [Figure 6](#)). As with the factory application of three-layer FBE–polyolefins, the polypropylene copolymer must be applied within the gel time of the FBE powder in order to ensure adequate chemical cross-linking and a good chemical bond between the two. It is the subsequent and final step in the field joint coating procedure that differentiates between each of the first five polypropylene field joint coating types listed.

1. The sintered polypropylene copolymer field joint coating application method involves the buildup of the copolymer coating, by flock spraying as a dry powder, making use of the residual heat in the field joint to melt, and coalesce the copolymer particles. As polyolefins have a low thermal conductivity, the total coating thickness that can be achieved is limited usually to less than 1 mm without the application of additional external heat in between successive copolymer powder applications. In addition, the final copolymer layer may be porous because of a lack of fusion between adjacent particles of powdered polyolefin, which have failed to reach their melt temperature.

2. In the coextruded polypropylene sheet method, the field joint area is wrapped with a sheet of polypropylene–polypropylene adhesive coextruded sheet. Preheating of the sheet is required as is further heating of the field joint area to ensure good fusion between the sheet and the flock-sprayed layer of adhesive applied previously. Sealing of the longitudinal and circumferential edges of the sheet by plastic extrusion welding is also required, using a polypropylene consumable, see **Figures 7 and 8**. Although this method is capable of giving a sound field joint coating with properties equivalent to those of the line pipe coating, it is time consuming to apply it correctly. It has been superseded by a second generation extruded polypropylene copolymer sheet, which is capable of bonding directly to the field joint area, the line pipe coating, and itself. This can be applied as a complete wrap, overlapping the factory coating circumferentially and itself axially, and avoiding the need for extrusion welding.
3. The injection molding of polypropylene at field joints has been considered for buried pipelines, but to date, has been used exclusively on offshore pipelines. It requires bulky and sophisticated equipment to both melt the polypropylene and pump it into the mold, which fits around the field joint area, see **Figure 9**. It consumes a lot of energy and is expensive compared with the alternative systems available. Nevertheless, it gives an extremely robust field joint with properties almost identical to the factory coating on the line pipe.
4. Of all of the polypropylene field joint coatings that have been developed, flame spraying is perhaps the most versatile as, in addition to field joints, it can also be used to coat fittings and preformed bends at a wide range of coating thicknesses. During flame spraying, the polypropylene copolymer powder is blown through the center of a circular gas flame under inert-gas pressure. The pressure of the inert gas propels the heat-softened polypropylene particles toward the substrate. The softened particles impact on the pipe surface coalescing with themselves and the existing layer of copolymer adhesive, see **Figures 10 and 11**. The application is a highly skilled process, as the heat input to the substrate and the sprayed powder need to be carefully controlled in order to buildup the coating thickness without compromising the quality of the coating. Too much heat can result in a reduction in the long-term environmental stability of the finished coating.
5. The coextruded polypropylene tape is the most recent development and is an extension of the

**Figure 7** Coextruded polypropylene sheet in place over the field joint.

**Figure 8** Final appearance after plastic welding at the horizontal and circumferential seams.

**Figure 9** Injection molded polypropylene field joint coating application to pipe test pieces.

**Figure 10** Flame spray application of polypropylene to pipeline field joints inside a weatherproof shelter.

**Figure 11** Close up of flame spray polypropylene application trial. Note the completed trial field joint coating in the foreground.

coextruded sheet method. Being more flexible than the sheet, it is applied to the field joint as a spiral wrap in the same way as a cold-applied tape. Good adhesion between successive spirals of the tape, between the tape and the pipe, and between the tape and the line pipe coating requires preheating of the pipe and the tape, and postheating of the applied wrapping. An example of the automated polypropylene tape application equipment is shown in [Figure 12](#).

#### 4.15.5 Pipeline Coatings for Thermal Insulation

In certain circumstances, it may prove necessary for a buried pipeline to be thermally insulated. The justification for thermal insulation will be

**Figure 12** Spiral wrapping of polypropylene coextruded tape.

determined by the nature of the product being transported and/or the condition the product needs to be in, at the point of delivery. For multiphase hydrocarbon flow lines, flow assurance may well be the major concern. Maintaining the product temperature above a certain level will ensure that neither wax deposition nor hydrate formation will jeopardize the product flow rate over the projected lifespan of the project. For gas pipelines, the gas delivery specification may include a minimum temperature to be maintained to avoid liquid drop out and attendant problems with fluid handling at the reception facilities.

It is a common misconception that applying a thermal insulation system will also prevent external corrosion of the pipe. In practice, thermal insulation systems are invariably breached by moisture, resulting in localized corrosion rates well in excess of those to be anticipated if no thermal insulation system were in place. In addition, with thermal insulation, any applied cathodic protection is unlikely to be effective because of the high electrical resistivity of the thermal insulation. It is a good engineering practice, therefore, to ensure that steel pipelines are protected using one of the coating systems previously described, before thermal insulation is applied.

The most commonly used thermal insulation systems for buried piping usually employ polyurethane foam as the insulant with an outer protective layer. This outer layer needs to be mechanically robust as polyurethane foam has a low compressive strength and is easily damaged. A well established factory application system used for district heating purposes comprises a high-density polyethylene (HDPE) outer pipe arranged concentrically over the transmission pipe using spacers.<sup>21</sup> The annular space between the

two pipes is filled with blown polyurethane foam. Temporary end caps ensure that the foam is not lost from the open ends of the HDPE pipe. At the field joints, the continuity of the thermal insulation must also be ensured. Various field joint insulation systems have been employed using some preformed polyurethane foam half shells with either heat shrink sleeves or cold-applied tapes to provide the outer protection for the foam. Because of the problems resulting from poor half shell fitup and correspondingly difficult field application procedures, track records with such systems have been indifferent, leading to severe corrosion in some cases. The use of such systems is difficult to justify on pipelines carrying hazardous products such as hydrocarbons.

A novel line pipe insulation system developed for a gas transmission pipeline in the early 1990s comprised of an FBE powder protective coating, 50–150 mm of polyurethane foam and an 8-mm poured polyurethane outer coating.<sup>22</sup> Using advanced polyurethane foam and liquid polyurethane application technology, each 12-m length of line pipe was first coated with FBE, then thermally insulated and the insulation was sealed. The insulation application process resulted in a tapered insulation profile at each end with an outer layer of solid polyurethane providing mechanical protection and a complete seal at the foam-coated pipe interface, see [Figure 13](#). During pipeline construction, the field joints were coated with FBE in the traditional manner (see earlier) and then thermally insulated using preformed foamed polyurethane half shells fitted around the joint area, and then fully encapsulated in liquid polyurethane pumped into suitably sized molds; see [Figure 14](#).

#### **4.15.6 Pipeline Coating Rehabilitation**

The decision to refurbish an external coating on an ageing, but still required, buried pipeline will normally be determined by an analysis of the results from a combination of the following: the leak history investigation, aboveground nonintrusive surveys (e.g., cathodic protection status), wall thickness measurements using intelligent pigs, and direct visual inspection of the condition of both the coating and pipe surface at a representative sample of bell holes. In many instances, the cost of excavation, pipe repairs and external coating refurbishment, and reburial will be prohibitive when compared against partial or total pipeline replacement. From a production standpoint,

**Figure 13** Thermally insulated line pipe awaiting pipeline construction.

**Figure 14** Moulded thermally insulated field joints.

the consequences of taking the pipeline out of service for extended periods of time also need to be addressed.

Once the decision to refurbish the pipeline has been reached, the selection of the equipment needed for the removal of the old coating, for repairs to the pipe and for surface preparation and new coating application, has to be made at an early stage. This is so that questions regarding the extent of pipe excavation can be addressed and sufficient clearance can be provided around the pipe for all of the required equipment to function fully as intended.

Proprietary line travel equipment exists for refurbishing external coatings on long continuous pipeline sections. This equipment incorporates separate devices for the removal of old coatings, abrasive blasting of the steel surface, and application of the new coating. Preference should be given to the use of

equipment that captures removed coating materials and spent abrasives for disposal, in accordance with local government legislation. Such equipment will often require a greater clearance around the pipe than usually required with manual methods of coating removal, surface preparation, and coating application.

The removal of old coatings will require one or more equipment types – scrapers, high-pressure water jetting ( $\leq 20\,000$  psi), abrasive blasting, etc., depending on the coating type and its condition. For optimum performance from the new coating, the final stage in the surface preparation process should be abrasive blasting. The ideal surface condition is one that complies with grade Sa2.5 in accordance with the visual standard in ISO 8501–1. An angular surface profile with minimum amplitude of  $50\mu\text{m}$  is an additional advantage. Although some coating material suppliers would claim this requirement to be unnecessary,<sup>23</sup> careful consideration of the pipeline operating conditions, diameter, and projected further life is required before this advice is to be considered viable.

Protective coatings used for the refurbishment of old pipelines include all of those considered in the previous sections of this chapter with the exception of FBE powder and two- and three-layer polyolefins. The application of these coatings employs too high a level of sophistication to be practical on a scale larger than applicable to field joints only.

Today, liquid-applied epoxy and polyurethanes, mainly solvents-free (see [Section 4.15.4.1](#)) tend to be the coatings most regularly chosen for pipeline coating rehabilitation, as these provide superior mechanical damage resistance particularly at elevated temperatures ( $\geq 50^\circ\text{C}$ ), and the potential for longer-term external corrosion protection when compared with the alternatives available.<sup>24,25</sup> However, where partial refurbishment of existing coatings is to be carried out, over short sections such as at bell holes, for example, considerations of compatibility with the existing coating, or materials availability, for example, may justify the use of one of the different generic alternatives available.<sup>26</sup>

#### 4.15.7 Quality Control During Coating Application

As with all protective coatings, the lifespan of those used to protect buried steel will be greatly enhanced by close attention to quality control during surface preparation and coating application. The cost of excavation and reburial on top of surface preparation and

coating application emphasize the need to ensure that the risk of premature coating failure is avoided.

The cornerstone of good quality is the coating specification. The specification should define the following:

1. What exactly is to be coated in terms of the boundary limits and interfaces with other work.
2. The responsibilities of the different parties involved in the work, not just those actually carrying out the surface preparation and the coating application. This includes those responsible for ensuring that the specification is followed and all quality control activities are completed, which is usually the coating contractor, the supplier(s)/manufacturer(s) of the coating materials and those responsible for rectifying any damage caused during handling and transportation.
3. The reference standards to which the work is to be carried out, including all quality control measurements and test procedures.
4. The specific materials to be used, both for surface preparation and coating application and the number and thickness of each coat.
5. All quality control measurements and tests, their frequency, and the results to be achieved.

The location where the work is to be carried out may well have a significant bearing upon the specification. Surface preparation and coating application in the factory have the major advantages over site work of (1) being independent of the weather and (2) not being confined to daylight hours, as power and light are normally readily available. Equipment can be more easily maintained and testing and inspection can be more sophisticated and rigorous compared with work on site. The specification should recognize the conditions under which the work is to be carried out and the constraints imposed accordingly.

Quality control tests during surface preparation should include visual assessments of the surface condition both before and after preparation. Visual standards are available against which to compare the surface of the prepared item before application of the first coat.<sup>3</sup> Inspection of the surface should also include the assessment of dust<sup>5</sup> and where items to be coated have been stored in coastal areas, the level of salt contamination.<sup>27</sup> For abrasive blasted surfaces, quality control tests should include the measurement of the surface profile.<sup>6</sup>

Quality control tests on applied coatings should always include as a minimum coating thickness,<sup>28</sup> holiday detection,<sup>29</sup> and adhesion. There are several standard test methods available for determining

the adhesion quality of thin-film coatings of limited flexibility.<sup>30–32</sup> For thicker, more flexible coatings, such as polyolefins, the quality of the adhesion is best determined using the peel adhesion test.<sup>17</sup> All of these standard adhesion test methods are destructive, requiring coating repairs at the test site. Thus it is often more convenient for coated test samples to be prepared in an identical manner so that the quality of the adhesion can be determined without incurring coating repairs on the work item. Such test samples can also be used to determine the resistance of the coating to cathodic disbondment.<sup>17,18</sup>

With multicomponent solvent free liquid-applied coatings such as polyurethanes and epoxies, it is also good practice to take cup shots of the mixed material at various stages during the coating application process. This is to verify that a consistent mixing ratio is being achieved within the coating manufacturer's recommended tolerances throughout the coating application process. The physical properties of the fully cured samples can be subjected to gravimetric analysis, hardness, tensile strength measurements, etc., to verify that the optimum mixing ratio is being achieved. This type of testing is particularly useful where the coating is being applied, using automated equipment such as that shown in **Figure 4** where there is a risk of the material going off ratio due to a component malfunction.

FBE powder coatings require a minimum substrate temperature for the coating to fully cure and provide optimum corrosion protection. It is therefore a standard practice to remove small samples of the applied coating from the substrate in order to confirm that full cure has been achieved. The removed coating samples are examined using a differential scanning calorimeter (DSC).<sup>33</sup> This equipment is able to determine the thermal characteristics of the coating, in particular, the glass transition temperature, from which the degree of cure can be ascertained.

It is very common for structures manufactured from steel and buried underground to have a design life in excess of 30 years. A sound coating selection process, good surface preparation, and coating application practice supported by a rigorous quality control system are necessary at construction if such aspirations are not to prove unrealistic.

### 4.16.1 Introduction

It is not always easy to apply the concepts of quality control, which have become routine on coating production lines, to new steel structures. In many steelwork fabrication shops, much of the day-to-day throughput does not require a high-performance paint system to be applied. For most major new constructions, however, a protective coating system is needed to ensure the best possible corrosion protection. It is for these types of project that painting inspection is an essential requirement. The full performance of any protective coating system will only be realized if it is applied to a well prepared surface, under suitable environmental conditions. The paint system must have good adhesion to the substrate and must be free from defects. Each individual coat must also be applied at the correct film thickness.

For most protective coating projects, therefore, the skill and diligence of the blasters and sprayers involved will determine whether a particular paint system will provide the long-term corrosion protection required or fail prematurely. Inspection of both surface preparation and each stage of paint application by a suitably trained, and preferably independent, painting inspector is the best way to ensure that the protective coating of new constructional steelwork or the maintenance painting of an existing asset is successful. The primary purpose of painting inspection, therefore, is to ensure that the coating specification is met fully by the contractor, on time and, wherever possible, on budget. Inspection is never a substitute for adequate supervision, nor is it a satisfactory way of overcoming the shortfalls of a badly written specification.

### 4.16.2 Duties of the Painting Inspector/Types of Inspection

#### 4.16.2.1 Introduction

The duties of a painting inspector will be determined by the scope of his engagement. As a minimum, the inspector will check and report that all elements of the coating schedule have been completed satisfactorily.

The painting inspector's duties will usually extend beyond this, however, to ensuring that the specification, as written, is met fully and that, if any deficiencies in workmanship are discovered, they are brought to the attention of the client at the earliest possible moment. It is important to note that a painting inspector has no power to order work to stop, unless the power has been delegated to him, which is unlikely.

For the high-performance protective coating systems specified today, some projects will require the maximum level of surface preparation and will benefit from continuous inspection at every stage. For many minor painting programs, however, less intensive inspection may be adequate. It is the responsibility of the client to determine the appropriate level of inspection needed and to make provision accordingly. One of the following three possible levels of inspection is usually selected:

- *Full inspection:* The inspector is on site throughout the project to witness that preparation and painting work complies with the requirements of the specification, at all times. Work is inspected at each stage of the program and only when formal approval has been given is the next coat of the paint system applied, for example. For the largest projects, more than one inspector may be needed.
- *Intermittent inspection:* The inspector is not on site at all times and observes work in progress at agreed intervals. Intermittent inspection is, by its nature, less costly than full inspection, but is also less complete.
- *Occasional inspection:* The inspector observes the initial work by the applicator and agrees the standard to be achieved for subsequent work. He then returns to site infrequently to inspect the work done and to check that the agreed standard of application has been maintained. Although the cost savings that can result on inspection are considerable, the overall benefit to the client technically is very much reduced.

The level of inspection chosen will be determined, most often, by the nature of the project and the complexity of the protective coating work involved. A strong case for full inspection on a minor maintenance painting program, therefore, or a relatively undemanding new construction project can rarely be made.

#### 4.16.2.2 Inspection Records and Reports

The compiling of adequate inspection reports is an important aspect of a painting inspector's duties. Inspection reports not only provide a record of progress on a contract, but also become a source of useful information when maintenance painting is due. In the event of an

unexpected coating failure, an investigation into the cause can often be moved forward more quickly, when access to inspection records can be provided.

The painting inspector will usually complete a daily inspection record and provide a weekly summary report. The inspector's daily and weekly records will be issued to the client and may also be circulated to other interested parties, as required. The permanent record of progress provided by the inspector will be retained on file by the client and, subsequently, will become an integral part of the archived project documentation. A daily paint inspection report will usually include, as a minimum, information on

1. The general weather conditions and the local ambient temperature, relative humidity, dew point, and steel temperature.
2. The location of the work area that day and the number of blasters and painters involved.
3. Whether surface preparation work is being undertaken and, if so, the condition of steel surface before and after preparation, together with details of the method of surface preparation used.
4. Whether paints are being applied and, if so, the product reference and the batch number of each paint coating, together with a note on their method of application.
5. While inspecting, a description of the inspection methods and instruments used, together with the results obtained.
6. Whether the requirements of the specification have been met fully in the areas inspected and, if not, the nature and extent of any noncompliance.

#### 4.16.2.3 Additional Inspection Services

Most specialist providers of painting inspectors will usually offer a number of additional services, when required, including

1. Constructive comments on the coating specification, wherever appropriate, to alert the client to any ambiguities, inaccuracies, or omissions.
2. A preliminary discussion on the painting contractor's proposed method of working and any foreseen health and safety hazards.
3. Liaison with the paint manufacturer directly on the coating products selected and any critical requirements for their successful application.
4. The drafting and presentation of an inspection schedule, setting out precisely how and at what stages of the coating program, inspection will be carried out and reported.

5. Where there is a requirement for precontract inspection of the blast cleaning and painting contractor's facilities and equipment, specialist providers of painting inspection will usually offer this preliminary service as well.

The purpose of a precontract inspection at works is to confirm that the facilities are adequate and that the equipment that will be used has been well maintained and is currently in good working order. The cleanliness of the paint shop and the tidiness of the paint store can often give a telling indication of the seriousness with which the workforce takes the surface preparation and protective coating of steelwork.

The purpose of a precontract inspection on site is to ensure that any scaffolding and access platforms needed will provide safe access to the work, that compressors are in good working order, that any temporary sheeting needed will be effective and that extraction equipment is available to remove solvent vapors and dust particles.

#### **4.16.2.4 The Importance of Precontract Discussions**

Precontract discussions involving the client, the main contractor, the steel fabricator, the painting contractor and, in particular, the painting inspection company can be invaluable, as they provide a forum in which potential problems with the program, as a whole, can be 'ironed out' before any work on the project commences. Precontract discussions enable agreement to be reached on, for example

1. Any features of the design that, if not modified, may be difficult to coat successfully.
2. Arrangements and facilities for the testing of materials, including coatings.
3. The measures to be adopted to reduce coating damage during handling, transport, and subsequent erection on site.
4. The chain of authority to be followed in cases of difficulty or disagreement.

When the minutes of such discussions are recorded accurately, they can serve as a useful adjunct to the contract.

#### **4.16.3 The Training and Certification of Painting Inspectors**

The protective coating of constructional steelwork has advanced technically in recent years, and as a

consequence, industry pressure for the development and provision of programs of formal training and certification of painting inspectors has increased. Initiatives over the last two decades, in both the United Kingdom and the United States, first to certificate painting inspectors and then to provide enabling training programs have culminated in the Institute of Corrosion's (ICorr) Painting Inspector Scheme in the United Kingdom and the National Association of Corrosion Engineers' (NACE) Coating Inspector Training and Certification Scheme. For both of these now well established certification schemes, candidates attain initially a Level 1 Certificate. With further study and verifiable work experience, inspectors can then progress to Level 2 and, ultimately, to Level 3 certification. For many high-profile, new construction projects and for programs of critical coating maintenance on important assets, the use of NACE- or ICorr-certificated painting inspectors has become very much the preferred option.

#### **4.16.4 Specific Aspects of Inspection**

##### **4.16.4.1 Initial Inspection of Liquid Paints and Blast Cleaning Abrasives**

Supplies of the liquid paints specified for a project and the blast cleaning abrasives to be used for surface preparation should be checked by the painting inspector initially to ensure that they are of the correct type, that they are being stored correctly, and that they have been supplied in sufficient quantities to allow surface preparation and paint application to proceed smoothly. For some projects, it may be a requirement of the inspection contract for tests on the paints to be performed, in a laboratory, to a predetermined schedule. In this event, the inspector may be required only to take the liquid samples needed for the testing program and forward them to the test house. Typically, the routine checks made by a painting inspector on liquid paints delivered to a steel fabricator's works, or to site, for a project will include the following:

1. Checking that the paints delivered correspond to the coating products specified, for example, manufacturer, product type, product name, and color.
2. Checking that the paints delivered are of the correct type for the method of application to be used, for example, spraying grade or brushing grade.
3. Checking that the paint store does not suffer from extreme temperatures and is both safe and secure.

Typically, the temperature inside the paint store should be above  $+3^{\circ}\text{C}$  and below  $+30^{\circ}\text{C}$ .

4. Checking that the paints have been delivered in sufficient quantities for the amount of steelwork to be coated (and, if not, that further supplies can be obtained quickly when needed).

The painting inspector should record the batch numbers and expiry dates of all paints held in the store. The subsequent withdrawal of paint, when coating work commences, should then be controlled and monitored by the inspector to ensure that the stocks are always rotated properly and that the paint used is always well within its shelf life.

When cans of paint are opened for use, the inspector will observe that they are first mixed thoroughly and that any settlement, if found, can be reincorporated into the bulk of the paint easily and satisfactorily. For two-pack paints, the inspector will observe that the base and hardener are always mixed together in the correct proportions and that any induction period before application is observed. The inspector will also ensure that any two-pack paints that cannot be applied within their pot life are discarded.

In cold weather conditions, it may be necessary to add small amounts of solvents to paints in order to lower their viscosity for spraying. Whenever any addition of thinners are made to the paints, the inspector will normally note the additions being made and ensure that they do not exceed, in percentage terms, the recommendations given by the manufacturer. Guidance on the preparation of samples of paints and coatings for testing and their subsequent examination may be found in BS EN ISO 1513.<sup>1</sup>

When abrasive blast cleaning is the method of surface preparation used, the inspector may be required to carry out checks on the abrasive itself. The extent of inspection of an abrasive will be determined by the requirements of the specification. As a minimum, however, it would be usual to check that the abrasive is of the correct type, for example, steel grit, steel shot, or copper slag, that it is of the correct particle size, and that it is dry. In the unlikely event that either the purity or the cleanliness of the abrasive is in doubt, then tests may be needed to determine, for example, the presence of foreign matter and the presence of water-soluble contaminants.

Guidance on test methods for metallic blast-cleaning abrasives may be found in BS EN ISO 11125<sup>2</sup> and guidance on test methods for nonmetallic blast-cleaning abrasives may be found in BS EN ISO 11127.<sup>3</sup>

#### 4.16.4.2 Inspection of Surface Preparation

The primary objective of surface preparation is to produce a clean surface to which the first coat of a paint system will adhere well. For protective coating systems on steelwork, an inspector may be asked to examine the initial condition of the steel surface and then to examine the condition of the steel surface after preparation for painting. He will usually inspect prepared surfaces for physical cleanliness, chemical cleanliness, and surface roughness (profile) by visual assessment and appropriate test methods. Constructional steelwork is prepared for painting, most often, by abrasive blast cleaning, hand- and power-tool cleaning, or high-pressure water jetting. Fabrication of the steelwork is likely to have involved both cutting and welding operations.

Inspection of the surface preparation of steelwork prior to painting has been assisted greatly by the development of relevant national standards over the past 40 years; most notably in Sweden, the United Kingdom, and the United States. These national standards have led, in more recent years, to the publication of four series of International (ISO) Standards. In the United Kingdom, these multipart ISO Standards have been issued by BSI as BS EN ISO 8501–8504. The second edition of a general introduction to these BS EN ISO Standards, BS 7079,<sup>4</sup> provides a concise overview of their scope and content. The inspector's working standards for the surface preparation of steelwork are laid out in Parts 1 to 4 of BS EN ISO 8501.

BS EN ISO 8501-1 specifies a series of rust grades and preparation grades (subsequent degrees of visual cleanliness) for uncoated steel surfaces. The various rust and preparation grades are defined by written descriptions and by photographs that are representative examples. There are twenty eight photographs in total. Four rust grades of uncoated steel, designated A, B, C, and D and three series of preparation grades, designated Sa, St, and Fl, according to the method of surface preparation used, are described and illustrated.

For abrasive blast cleaning (Sa series), four preparation grades are designated as follows:

- Sa 1 Light blast-cleaning;
- Sa 2 Thorough blast-cleaning;
- Sa 2 1/2 Very thorough blast-cleaning;
- Sa 3 Blast-cleaning to visually clean steel.

For hand- and power-tool cleaning (St series), two preparation grades are designated as follows:

- St 2 Thorough hand- and power-tool cleaning;
- St 3 Very thorough hand- and power-tool cleaning.

For flame cleaning (Fl), there is only one preparation grade, namely

- Fl Flame cleaning.

BS EN ISO 8501-1 is an important inspection tool. It enables the inspector to compare the appearance of uncoated steel, and the same steel after it has been prepared for painting by one of these methods, with internationally agreed written descriptions and representative photographic examples.

A number of different abrasives may be used to blast clean steelwork. If the abrasive used is nonmetallic, dark in color, and becomes embedded in the surface profile, it can alter the visual appearance of the surface finish. In contrast, some hard, metallic abrasives can create an apparently darker surface finish as a result of shadows in deep-sided pits. To assist the inspection of such surfaces, a further six photographic examples of such effects have been included in BS EN ISO 8501-1, as an informative annex.

BS EN ISO 8501-2:2001 complements BS EN ISO 8501-1, and in a similar way, provides written descriptions and representative photographic examples of steel surfaces after the localized removal of previous paint coatings. BS EN ISO 8501-2 provides detailed guidance on the visual inspection of surface preparation in, for example, a maintenance painting program where the complete removal of all previously applied coatings may not be required.

Welds, cut edges, and minor imperfections in steelwork are often starting points for corrosion. Inspection of the surface preparation of these areas, prior to paint application, is assisted by BS EN ISO 8501-3. The standard defines three preparation grades for making steel surfaces with imperfections suitable for application of paints and related products. For each grade, requirements for the preparation of commonly found imperfections are tabulated and are also illustrated with line drawings.

While dry abrasive blast cleaning, and to a lesser degree, low-pressure water/abrasive blast cleaning are still used widely for the surface preparation of steelwork, the use of high-pressure water jetting has increased in recent years, as it offers an effective method of removing rust, previous coatings, foreign matter, and water-soluble contaminants, all at the same time.

BS EN ISO 8501-4 is a new standard that has been developed to stand alongside BS EN ISO 8501-1 and provide a comparable tool for the visual assessment and inspection of initial surface conditions, preparation

grades and flash rust grades on steelwork prepared for the application of paints and related products by high-pressure water jetting. The preparation grades are again defined by written descriptions and photographs that are representative examples within the tolerances of each grade, as described in words. There are 23 photographs in total.

Specifically, five initial surface conditions are defined, three of which are applicable to degraded paint coatings and two of which are applicable to damaged prefabrication primers. Three preparation grades for each initial surface condition, after partial or full removal of previous paint coatings by high-pressure water jetting, indicate the degree of cleaning required. Three grades of flash rusting of the steel surface that develop when high-pressure water jetting is the method of preparation used are also specified.

#### **4.16.4.3 Inspection of Surface Profile**

Preparation of steelwork by abrasive blast cleaning not only removes surface contaminants, such as rust and mill scale, but also introduces a surface profile. The magnitude of the surface roughness (peak-to-trough height) that results when this is the method of surface preparation selected will be determined by the particle size of the abrasive used and the air pressure at the nozzle. Measurement of surface profile and checks each day on the air pressure at the nozzle of the blast cleaning equipment being used will form part of the inspector's duties on many contracts. Ensuring that the specified surface profile is achieved is important. If the profile is too low, the adhesion of the coating may be compromised. If the profile is too high, there is a danger that the tallest peaks will not be covered adequately by the coating and so will corrode in service.

Surface comparators are used most commonly today by inspectors for assessing the grade of surface profile on steel surfaces. In parts 1-4 of BS EN ISO 8503, the requirements for these comparators are specified and two laboratory procedures for their calibration are defined. BS EN ISO 8503 is in five parts, and in part 5, an alternative method of measuring surface profile on site with the aid of replica tape and a micrometric gauge is defined.

Two surface profile comparators have been specified in BS EN ISO 8503: Reference Comparator 'G' is for grit-blasted surfaces and Reference Comparator 'S' is for shot-blasted surfaces. Each comparator has four segments (numbered 1-4) each of a

peak-to-trough height defined by nominal values and associated tolerances. For Comparator 'G', for example, the nominal values and tolerances are as follows:

Segment	Nominal reading ( $\mu\text{m}$ )	Tolerance ( $\mu\text{m}$ )
1	25	3
2	60	10
3	100	15
4	50	20

'Fine', 'medium' and 'coarse' profiles are then defined, as follows:

- Fine: Profiles equal to segment 1 and up to but excluding segment 2;
- Medium: Profiles equal to segment 2 and up to but excluding segment 3;
- Coarse: Profiles equal to segment 3 and up to but excluding segment 4.

In use, the inspector compares the blast-cleaned surface to be graded visually with the segments on the appropriate comparator and determines whether the work surface is 'fine,' 'medium,' or 'coarse.' This relatively simple approach to grading surface profile is generally adequate.

Many specifications continue to rely on the final inspection of the blast-cleaned surface as the procedure for acceptance. This approach is reasonable as long as the blast-cleaning equipment used has been well maintained and is functioning satisfactorily. When problems do arise with the equipment, however, the inspector may be required also to check the air pressure at the blasting nozzle and the quality of the compressed air emitted. The checks required are simple and can be performed quickly.

In order to check the air pressure at the nozzle of the blast-cleaning equipment, the hypodermic needle of a special pressure gauge is inserted into the blasting hose, close to the nozzle, and the pressure is measured. The small hole made in the hose by the hypodermic needle seals quickly when the needle is withdrawn and the subsequent operation of the hose is not compromised. Typically, the air pressure required at the nozzle is 80–100 psi (550–690 kPa).

The compressed air itself must be clean and dry, in order not to contaminate the blast-cleaned steel surface. The quality of the compressed air can only be checked by the inspector, with the abrasive supply switched off. A clean white cloth (or filter paper) placed in front of the nozzle allows the inspector to see unwanted water

and oil contaminants. If any contamination is found, the inspector will then require the contractor to check his equipment and rectify the problem.

#### 4.16.4.4 Inspection of Steel Surfaces for Chemical Cleanliness

For steelwork that will be coated and then exposed, in service, to aggressive industrial and marine environments, the chemical cleanliness of the steel is of equal importance to the physical cleanliness of the surface and the surface roughness. The BS EN ISO 8502 Series of Standards addresses this requirement and defines field and associated laboratory test methods to determine both the physical and chemical surface cleanliness of steel substrates before application of paints and related products. There are currently nine parts to the 8502 Standard.

The test methods in 8502 describe suitable field procedures for the extraction of soluble ferrous salts and the analysis, on site, of the extract for the presence of ferrous ions, chloride ions, and sulfate ions. In the case of chloride ions, a procedure intended only for use in the laboratory is also provided. The field test methods include the use of ion-detection tubes for chlorides, measurement of conductivity for water-soluble salts, and measurement of turbidity for water-soluble sulfates. There is also a field test method for the refractometric determination of moisture; guidance on estimating the probability of condensation on a steel surface and a simple procedure, involving the use of pressure-sensitive tape, to determine whether a steel surface prepared for painting is free from dust and debris.

While it may be a requirement for an inspector to test steel surfaces for the presence of soluble ferrous salts after preparation for painting, it may not be necessary for him/her to determine whether soluble ferrous salts, when found, are chlorides or sulfates, for example. In such situations, the potassium ferricyanide test, first described in British Standard Code of Practice 5493,<sup>5</sup> is still often relied upon. For this test, an area of the blast-cleaned steel surface is moistened with distilled water, and when the surface is almost dry, a test paper that has been impregnated previously with a dilute aqueous solution of potassium ferricyanide is placed on the steel surface. Deep blue spots (a Prussian blue complex is formed) develop quickly on the yellow test paper wherever ferrous salts are detected. The test method is qualitative and very sensitive. It provides an easily conducted pass/fail procedure for routine site inspection work.

#### **4.16.4.5 Monitoring of Ambient Conditions**

An important aspect of the inspection of both surface preparation and paint application is the monitoring of ambient conditions. Specifications may require abrasive blast cleaning to be carried out under ambient conditions that will ensure that the freshly blast-cleaned surface will not deteriorate quickly and will be preserved until paint can be applied a few hours later. Specifications may also require paint to be applied only under defined ambient conditions.

The painting inspector will normally monitor the air temperature, the steel temperature, and the relative humidity, two or three times during the working day. On some projects, continuous measurement of air temperature and relative humidity may be provided by the client and the data logged electronically. For most projects, however, the monitoring of ambient conditions remains the duty of the inspector. Typically, a painting inspector will use a whirling hygrometer to determine the relative humidity and also to measure the air temperature. A contact thermometer will be used to measure the surface temperature of the steel. From the relative humidity, the dew point will then be calculated and recorded.

Specifications will usually require that steel temperatures should be at least 3 °C above the dew point, in order to avoid the possibility of moisture condensing on the work surface during preparation and painting operations. Relative humidity not greater than 85% and ambient air temperature not less than 4 °C are also usually prescribed. Ambient conditions outside these limits or deteriorating weather conditions that, it can be anticipated, will lead quickly to rainfall or relative humidity and air temperature outside the prescribed limits will be reasons for the inspector to advise the painting contractor to cease blast cleaning and painting.

#### **4.16.4.6 Inspection during Paint Application**

Monitoring paint application is an important aspect of a painting inspector's duties. The inspector will record climatic conditions; ensure that the paint is applied in accordance with that specified; and note that the correct method of application is being used. Application methods will depend on the type of coating product, the nature of the substrate, and the surface area to be painted. For most constructional steelwork, the method of paint application will be airless spray.

Paints almost always need to be mixed before being applied, to ensure that there has not been any settlement of pigment in the can. In the case of two-pack paints, thorough mixing of base and hardener, in the correct proportions, is essential. Thinning of some paints may also be needed prior to spray application, especially in colder winter months. The inspector will ensure that all of these procedures are carried out correctly and at the appropriate times.

A primer needs to cover the entire surface profile of the steel substrate and each coat of the paint system applied subsequently needs then to cover all areas completely and needs to be as uniform as possible in thickness. During paint application, therefore, the inspector may wish to measure the wet-film thickness of paint being applied. He should need only to make such checks infrequently, when the work is progressing smoothly, as the painters themselves should be checking wet-film thicknesses regularly as they proceed. Simple measurements with a wet-film thickness comb gauge are all that is required.

As the paint application progresses from primer to intermediate coats and finish, the inspector will ensure that each over-coating interval stated on the paint manufacturer's technical data sheet is observed and that any particulate contamination on intermediate painted surfaces, should it occur, is removed and is not painted over. The diligence of the painting inspector during the paint application phase of a project will influence, to a significant extent, the potential of the paint system ultimately to achieve its expected level of performance in service. A good rapport with the painting supervisor is always beneficial during this phase of the work program.

#### **4.16.4.7 Inspection after Paint Application**

When the paint system has been built up satisfactorily and has cured, the painting inspector can progress to the final phase of his inspection duties. Key requirements such as total dry film thickness, adhesion between individual coats, and curing of the paint system, as a whole, will all now need to be checked and reported. In addition, the inspector may be required to check the coating system for freedom from pinholes and to conduct other specific tests, if required by the client.

Methods for the measurement of paint film thickness are described in BS EN ISO 2808.<sup>6</sup> The procedure for checking nominal dry-film thickness is usually agreed between the inspector and his client.

Unless agreed otherwise, individual dry-film thicknesses of less than 80% of the nominal dry film thickness will not be acceptable. Values between 80% and 100% of the nominal dry-film thickness are acceptable, provided that the overall average value is equal to or greater than the nominal dry-film thickness. It is usually recommended that the dry-film thickness of a coating should not exceed three times the nominal film thickness.

These guidelines give the inspector a framework in which to analyze his/her results and to define any areas where coatings have been found to be either too thin or too thick. It is generally not the case that 'thicker is better.' Excessively thick films of paint and coatings will usually sag and may take an excessively long time to achieve full cure.

Good adhesion of the primer to the substrate and good adhesion of subsequent coats one to another is a prime requirement of a protective coating system and will usually be checked by the painting inspector. Guidance on cross-hatch adhesion tests is provided in BS EN ISO 2409<sup>7</sup> and guidance on pull-off adhesion tests is provided in BS EN ISO 4624.<sup>8</sup> As all adhesion testing is destructive, the inspector will not carry out more adhesion tests than required. On many painted surfaces, a simple St Andrews Cross cut with a sharp knife will give a good indication of poor paint adhesion and prompt the inspector to investigate further.

The full properties of a protective coating system will not be achieved if the paints have not cured properly. An inspector will usually use a solvent-rub test to determine whether, or not, a coating has achieved a full cure. Methyl ethyl ketone is the solvent used most often. Any softening or loss of coating during the test indicates an incomplete cure.

In addition to specific coating tests, an inspector will also examine painted surfaces visually for good coverage, uniformity of color, and for obvious defects such as sagging, wrinkling, and pinholes. The absence of pinholes is particularly important where protective coating systems are required to provide chemical resistance and barrier properties. Checks for the

presence of pinholes can be made by the inspector with a low-voltage or a high-voltage pinhole detector, as appropriate. High-voltage pinhole detectors need to be used with caution and understanding. If the voltage is set too high, there is a risk that the instrument will introduce small holes in the coating rather than detecting them.

#### 4.16.5 Concluding Remarks

The demand for well trained, certificated painting inspectors has increased in recent years, as the importance of thorough surface preparation has been recognized fully and advances in paint technology have led to the introduction of new generations of protective coating systems. Painting inspection can not only provide quality control throughout a painting contract but also ensure that the specification is met and that the client's expectations for robust corrosion protection are delivered.

### 4.17.1 Coating Failures and Defects

Coatings can be very complex materials and their principal constituents are resin, tinting pigments (colorants), and solvent. Other ingredients can be extender pigments (fillers), nonreactive diluents, thixotropes, curing agents, catalysts, film forming agents, etc. Not all coatings will contain all of the different types of ingredients, but most are complex mixtures that have to be carefully formulated to satisfy the design and performance criteria. The percentage by weight of a particular ingredient will vary between the type of coating and the supplier of the coating.

The coatings, single pack, two pack, or three pack, are mixed in the correct proportions for the two and three pack materials prior to application as a thin film by various methods. The application can take place at different levels of surface preparation under a wide range of environmental conditions that can vary from one part of a structure to another.

The applied coating after curing would be expected to retain its cosmetic qualities and perform and protect the substrate from the general elements such as variable levels of heat, cold, and humidity as well as wind, rain, sunlight, and oxygen. Coatings may also be subject to special conditions such as immersion in seawater or chemicals such as a specialist tank lining.

Considering all the variables, it is inevitable that some coatings fail earlier than anticipated. Coating defects may also be expected; however, this may not necessarily lead to a coating failure. For example, alligatoring may be considered as a coating defect,

but the system will still perform, and therefore, this defect does not necessarily constitute a coating failure.

In general terms, a coating failure can be related to formulation deficiencies, application problems, inadequate surface preparation, or external factors such as exposure to an environment to which it is not resistant. Coating failure is not always attributed to a single source, and often a number of contributing factors have to be considered in evaluating the breakdown mechanism. Coating defects normally fall into three categories: those arising during application such as sagging and cissing, those arising after application but prior to service entry such as blushing and wrinkling, and those appearing after entry into service such as chalking.

Probably the most common reasons for coating failure are inadequate surface preparation in terms of applying the coating to a lower standard of preparation than it was designed for, inadequate correction of steel defects, and inadequate removal of soluble salts. The coating failure could therefore be attributed to poor workmanship and/or incorrect specification requirements.

Application-related failures are common, particularly in the industrial and marine coatings industry where basic application faults, such as inadequate film thickness, misses, lack of stripe coating, incorrect over coating times, and inadequate curing times and temperatures prior to entry into service, frequently lead to early coating failure.

Coating selection is important; many coating failures being related to improper coating selection for

the specific environment to which it would be exposed, that is, the use of a product for a purpose for which it was not designed. Environments can also change with time, a prime example being tank linings on chemical carriers where variables of different cargoes, different temperatures, and tank cleaning on a cyclic basis place great stress on the coating system.

No matter how carefully a coating is formulated, laboratory testing is relied upon, to a great extent, to simulate in-service conditions and the results, together with those from field trials, are used to evaluate the coating prior to launch. Laboratory testing, however, cannot cover all of the in-service variables, and in addition, has to be of an accelerated nature; hence, only long-term use of the product is likely to highlight any formulation problems.

The following examples of coating failures and defects have been chosen to illustrate how coatings can fail prematurely or exhibit application defects. The photographs are examples only, as the type of failure or defect could manifest itself in a different way. It is not intended to make the reader an instant 'paint expert,' as the establishment of a failure mechanism is often difficult because of the number of potential contributory factors.

#### **4.17.1.1 Adhesion Failure (Delamination/Flaking)**

**Description:** Flaking, generally accepted as the detachment of the paint system from the substrate, and delamination, used to describe intercoat detachment in a multicoat system, are both forms of adhesion failure where a coating has failed to adhere to the substrate or the underlying paint coating.

**Probable causes:**

Adhesion failures can be as a result of either internal stress alone or internal stress plus the exacerbating effect of one or more other factors. The contributory factors could be related to formulation, inadequate surface profile, surface contamination, exceeding over-coating times, application to a glossy paint surface, amine bloom, incorrect surface preparation, and differential expansion/contraction of the paint coating and the substrate, particularly in the painting of timber.

#### **4.17.1.2 Alligatoring (also Known as Crocodiling)**

**Description:** Very large (macro) checking or cracking that resembles the skin of an alligator or crocodile. Cracks may penetrate to the undercoat, but generally not down to the substrate.

Probable causes: Internal stresses in the coating where the surface shrinks faster than the body of the paint film. Can be caused by excessive film thickness and limited paint flexibility and on paint systems having a flexible undercoat with a hard topcoat.

#### 4.17.1.3 Aluminum Corrosion

Description: Blistering and/or lifting of the paint coating because of the formation of aluminum corrosion products under the paint.

Probable causes: Pinholes in the coating, porosity of flame-sprayed aluminum, or insufficient coating thickness.

#### 4.17.1.4 Bittiness

Description: Film contaminated by particles of paint skin, gel, flocculated material, or foreign matter, which project above the paint surface to give a rough appearance. The term *Pep-pery* is used when the bits are small and uniformly distributed.

Probable causes: The main cause is contamination within or on the surface of the paint film by paint skin, gelled particles, airborne sand and grit, or contamination from brushes or rollers.

#### 4.17.1.5 Bleaching (also see [Fading](#))

Description: Total loss of the color of a coating.

Probable causes: Bleaching due to weathering or chemical attack.

#### 4.17.1.6 Bleeding (also Called 'Bleed Through')

Description: Staining of a paint film by diffusion of a soluble, colored substance from the underlying paint to give undesirable discoloration or staining. Very often, this is seen where bitumen or tar-based products are overcoated with alkyd-based or other conventional topcoats. It can also occur with emulsion paints.

Probable causes: 'Bleed through' is generally a full or partial redissolving of the previous coat and can happen when strong solvents are used in the topcoats.

**4.17.1.7 Blistering**

**Description:** Dome-shaped projections in the dry paint film through local loss of adhesion from the underlying surface. The blisters may contain liquid or gas, or may be dry.

**Probable causes:**

Osmotic blistering is commonly associated with the presence of soluble salts, soluble pigments, retained solvents, or the absorption and retention of low molecular weight water-miscible solvents, typically from the carriage of chemical cargoes. Nonosmotic blistering, commonly described as cathodic blistering, is often seen as a circular pattern of blisters around a coating defect where the substrate is exposed. Non-osmotic blistering can also occur due to a cold-wall effect producing condensation. Where coatings are used with cathodic protection, hydrogen production is possible and the resultant hydrogen vapor pressure could produce blisters.

**4.17.1.8 Bloom (Blush)**

**Description:** A hazy deposit on the surface of the paint film, resembling the bloom on grape resulting in a loss of gloss and a dulling of the color.

**Probable causes:**

Paint film exposed to condensation or moisture during curing (common phenomenon with amine-cured epoxies). Incorrect solvent blends can also contribute to blooming.

**4.17.1.9 Bridging**

**Description:** The covering over of unfilled gaps such as cracks or corners with a film of the coating material. This causes a weakness in the paint film, which may crack, blister, or flake off.

**Probable causes:**

Poor application, high-viscosity paint, or failure to brush paint into corners and over welds.

#### 4.17.1.10 Brush Marks (also Laddering, Ladders, or Ropiness)

**Description:** Undesirable ridges and furrows that remain in a dry paint film after brush application where the paint film has not flowed out. May be found as a cross-hatch pattern (laddering) where alternate coats have been applied in opposite directions. Pronounced brush marks are known as ropiness.

**Probable causes:** Viscosity of material may be too high for brush application, incorrect thinners used in the paint, inadequate mixing, or poor application technique. Two-pack paints may have exceeded their application pot-life.

#### 4.17.1.11 Bubbles or Bubbling

**Description:** Bubbles within a paint film appear as small raised blisters and may be intact or broken to leave a crater. They are found in excessively thick paint films, especially if spray applied, and also with roller application. This defect should not be confused with blistering.

**Probable causes:**

Trapped air/solvent within the coating, which is not released before the surface dries. They are also associated with factory-applied coatings where application is by dipping, electrodeposition, or roller coating.

#### 4.17.1.12 Chalking

**Description:** A friable, powdery layer on the surface of a paint film, often associated with a change of color or fading. Chalking rates vary with pigment concentration and choice of binder, and are a known characteristic of certain paints for example, amine- or amide-cured epoxy paints.

**Probable causes:**

The deterioration of the paint binder on exposure to weathering and/or UV light, leaving a powdery layer of underbound pigment at the surface.

#### 4.17.1.13 Checking (also see [Cracking](#))

**Description:** Fine cracks that do not penetrate to the substrate. Some checking can be so minute that it is impossible to see without magnification.

Probable causes: Typically, a formulation and/or a specification problem where the paint has limited flexibility. Surface stresses are developed, which cause the surface of the paint film to become brittle and crack.

#### **4.17.1.14 Cheesiness (Soft Coating)**

Description: The coating remains soft, even after a prolonged drying time.

Probable causes: Wrong mixing ratio for two-pack paints, too low a drying/curing temperature, or excessive solvent retained within the coating.

#### **4.17.1.15 Cissing (also Referred to as Crawling)**

Description: Surface breaks in a wet paint film, where the paint has receded to expose the underlying substrate, because the paint is unable to wet-out the substrate. The individual areas involved can be very large.

Probable causes: Surface contamination by either moisture or foreign matter such as oil, grease, silicone, etc. and is also known to happen when incorrect solvent blends have been used.

#### **4.17.1.16 Cobwebbing**

Description: The production of fine filaments instead of normal, atomized particles when some solutions of high-molecular weight polymers are sprayed.

Probable causes: Too high a viscosity with some types of polymer solutions.

#### **4.17.1.17 Cracking (also see [Alligatoring](#) and [Checking](#))**

Description: Paint coatings with visible cracks, which generally penetrate to the substrate. Cracking comes in several forms and ranges from minor cracking to severe cracking.

Probable causes:

Cracking is generally related to internal stress within the body of the coating. Factors involved in cracking are formulation, high film thickness, thermal cycling, substrate geometry, substrate movement, ageing, absorption/desorption of water or chemicals, and inadequate surface profile. One or more contributory factors exacerbates the internal stress in the coating.

#### 4.17.1.19 Crowsfooting (also see [Wrinkling](#))

Description: The development of small wrinkles in the paint film, which occur in a pattern resembling that of a crow's foot.

Probable causes:

Usually due to the surface drying rapidly to form a skin, which then wrinkles as the solvent slowly evaporates from the soft, underlying paint layer.

#### 4.17.1.18 Cratering

Description: The formation of small bowl-shaped depressions in the paint film, which are not to be confused with cissing.

Probable causes:

Trapped air bubbles that have burst to leave small craters as the coating dries and the coating has had insufficient time to flow out as a uniform film.

#### 4.17.1.20 Delamination (also see [Adhesion Failure](#) and [Flaking](#))

Description: Loss of adhesion between coats of paint.

Probable causes:

Provided compatible paint materials have been used, delamination defects are generally related to contamination between coats, including amine bloom, exceeding overcoat times, or application to a glossy surface.

**4.17.1.21 Dryspray (also see [Overspray](#))**

**Description:** Rough and uneven finish to the surface of the paint film where the particles are insufficiently fluid to flow together and are often poorly adhered.

**Probable causes:** Incorrect spray application, for example, gun distance. Also associated with fast drying products and too high an application temperature.

**4.17.1.22 Efflorescence**

**Description:** The formation of a white (powdery) substance on the substrate of concrete, brick, masonry, and plaster, or on the surface of the paint. The efflorescence, which comes from the migration of salts, can lift the paint from the substrate where impermeable films are involved.

**Probable causes:** Soluble salts within the substrate. Moisture brings the salts to the surface of the substrate, resulting

in coating adhesion failure, or they deposit on the coated surface where more porous films are involved.

**4.17.1.23 Erosion**

**Description:** Selective removal of paint films from areas of high spots.

**Probable causes:** The wearing away of the paint film by various elements such as rain, snow, wind, sand, etc. and found to be more prominent on brush applied coatings because of the uneven finish.

**4.17.1.24 Fading (also see [Bleaching](#))**

**Description:** Gradual decrease in the color of the paint when exposed to sunlight/weather, which tends to occur more rapidly in the presence of moisture and may be accompanied by a loss of gloss. In some situations, it may resemble chalking but without the powdery surface.

Probable causes: Incorrect pigmentation, the use of organic pigments, atmospheric contamination, or a porous substrate.

#### 4.17.1.25 Filiform (Corrosion)

Description: Random threads of corrosion that develop beneath thin lacquers and other coating films from a growing head or point. Often seen on old 'tin' food cans with thin electroplating, but also seen on painted aluminum and other surfaces.

Probable causes: Contamination on the metallic substrate or damage to the coating, which allows a corrosion cell to develop at the tip and advance under the coating.

#### 4.17.1.26 Flaking (also see [Delamination](#) and [Adhesion Failure](#))

Description: A form of adhesion failure where the paint flakes from the substrate, which is a familiar sight on wood substrates and on galvanizing.

Probable causes: Incorrect paint system used. Either none or incorrect pretreatment

used for certain substrates such as nonferrous or galvanized. May also be attributed to differential expansion and contraction of paint and substrate, for example, wood, and can be the result of the ageing of the paint system.

#### 4.17.1.27 Flocculation

Description: The development of loosely coherent pigment agglomerates in a coating material.

Probable causes: Nonuniform pigment dispersion, which results in the pigments forming agglomerations, arising from the use of unsuitable thinners, inadequate mixing, or inappropriate surfactants.

#### 4.17.1.28 Flooding (also see [Flotation](#))

Description: A defect that appears soon after application due to pigment separation, the visual appearance being a change of color where the affected area dries to a different shade than that of the remainder of the surface.

Probable causes: Pigment separation and settlement.

#### 4.17.1.29 Flotation (also see [Flooding](#))

Description: Occurs in colored materials containing mixtures of different pigments and closely resembles flooding, although a mottled or streaky effect is produced when the different pigments separate.

Probable causes: The mottled effect, which is visible to the eye, is caused by the separation of the different colored pigments and may also result from the addition of excessive thinners.

#### 4.17.1.30 Grinning (also see [Grinning Through](#))

Description: The underlying surface is visible through the paint film due to inadequate hiding power of the coating material. It is sometimes called grinning-through and is often seen where dark colors are overcoated with lighter colors.

Probable causes: Low film thickness of topcoat, poor opacity and covering power of topcoat, or strong color of the penultimate coat.

#### 4.17.1.31 Grit Inclusions

Description: Particles of grit and dust embedded within or adhering to the surface of the coating system.

Probable causes: Failure to remove used blast cleaning abrasive from the surface prior to the application of the paint. Contamination of the wet primer or undercoat with abrasive from other blast-cleaning operations, wind blown grit particles adhering to the topcoat, or poor housekeeping.

#### 4.17.1.32 Growth (on the Surface of Paint Film)

Description: Growth and attachments of natural organisms to the surface of finished products, which vary in form, size, and lifespan, for example, algae, mosses, etc.

Probable causes: Generally, natural organisms within moist, wet, or immersed conditions. Growth may continue after attachment.

#### 4.17.1.33 Incorrect Coating System

Description: An unsuitable or incompatible coating system has been used that results in rapid failure.

Probable causes: The use of incompatible or unsuitable coating materials.

#### 4.17.1.34 Impact Damage (Star Cracking)

Description: Cracks that radiate from a point of impact.

Probable causes: Impact damage to a relatively brittle coating, which is often seen on glass fiber reinforced plastics.

#### 4.17.1.35 Lamination or Shelling (of Cast Iron)

Description: The photograph shows flaking or shelling of sections of cast iron

from the surface that has been overpainted, which has led to subsequent rust staining.

Probable causes: Failure to remove or treat delaminated sections prior to the application of the coating system.

#### 4.17.1.36 Misses/Skips/Holidays

Description: Exposed areas of substrate or previous coat when the intention was to coat the entire area. Could be confined to a single coat in a multi-coat paint system.

Probable causes: Poor application techniques or a lack of quality control, or both.

#### 4.17.1.37 Mud Cracking

Description: The dried paint film has the appearance of a dried-out mud bath where the cracks can vary in size and amount, but form a network of cracks.

**Probable causes:** Generally, overapplication of heavily pigmented primers such as inorganic zinc silicates or water-based coatings, although it can occur with other systems that are thickly applied.

#### **4.17.1.38 Orange Peel (also Known as Pock-Marking)**

**Description:** The uniform pockmarked appearance, in particular, of a sprayed paint film, in which the surface of the paint film resembles the skin of an orange.

**Probable causes:** Failure of the paint film to flow out. Usually caused by poor application techniques or by incorrect solvent blend.

#### **4.17.1.39 Overspray (also see [Dry spray](#))**

**Description:** Small particles of paint adhering to the surface of the previous dry

coat, generally adjacent to the area being sprayed, and often appears as a pebbly surface, similar to dry spray.

**Probable causes:** Particles of wet paint falling outside of the spray pattern, too rapid a solvent evaporation, or spray application under windy conditions.

#### **4.17.1.40 Peeling (also see [Flaking](#))**

**Description:** Similar to flaking, although peeling tends to involve soft and pliable coatings that can be pulled away from, or spontaneously flake away from the substrate or from between coats because of loss of adhesion.

**Probable causes:** Peeling is due to a reduction in bond strength of the paint film because of inadequate surface preparation, contamination, or incompatibility of coats.

#### 4.17.1.41 Pinholes

**Description:** The formation of minute holes in the wet paint film during application and drying due to air or gas bubbles that burst giving rise to small craters or holes, which fail to coalesce before the film dries.

**Probable causes:** Solvent or air entrapment within a paint film, which is a common problem when coating porous substrates such as zinc-filled primers, zinc silicates, and metal-sprayed coatings. Pinholes can also be caused by incorrect spray application or incorrect solvent blend.

#### 4.17.1.42 Rain Damage – Water Spotting

**Description:** Craters and water marks on the surface of the paint film, caused by rain or heavy condensation.

**Probable causes:** Rain falling on a freshly painted surface causes craters and/or water marks to form on the surface before it has hardened sufficiently.

#### 4.17.1.43 Rippled Coating

**Description:** A rippled effect on the surface of the paint.

**Probable causes:** Strong wind blowing across the surface of wet paint causes it to ripple and this occurs on the underside; the ripples can hang down in the form of small stalactites. Can also be caused by poor application techniques.

#### 4.17.1.44 Runs or Sags (also Described as Curtains or Wrinkles)

**Description:** The downward movement of paint that appears soon after application to vertical surfaces because of excessive paint application and appears as tears, or in severe situations, it may be described as curtains.

**Probable causes:** Overapplication of paint, addition of excessive thinners, lack of or wrong curing agent, and in extreme circumstances, could be a formulation problem.

**4.17.1.45 Rust Rashing (to Thermal Spray Coating)**

**Description:** Spots of rust develop within the pores of sprayed metal coating, similar to rust spotting of a paint film.

**Probable causes:** A phenomenon that can develop on aluminum thermal-sprayed coatings soon after application when moisture is absorbed into the metal coating and reacts with the ferrous substrate. Early sealing with an appropriate coating prevents such events.

**4.17.1.46 Rust Spotting (also Referred to as Rash Rusting)**

**Description:** Fine spots of rust that appear on a paint film, usually a thin primer coat, which frequently starts as localized spotting, but rapidly spreads over the surface.

**Probable causes:** Where the rust spotting emanates from the substrate, low film

thickness, pinholes, and defects in the steel such as untreated laminations, or too high a surface profile causing penetration of peaks through a paint film are probable causes. Where the rust spotting does not penetrate to the substrate, it is probably from the metallic contamination of a coated surface by ferrous grinding debris.

**4.17.1.47 Rust Staining**

**Description:** A red/brown staining on the surface of the paint.

**Probable causes:** Water run-off from a rusty surface adjacent to a soundly coated surface. Rust staining occurs when the rust is wetted-out and contaminated water runs over and discolors other items or locations. It is usually more of an eyesore than a defect where the coating itself may not be defective, only stained.

#### 4.17.1.48 Saponification

**Description:** The coating appears to be soft and sticky, and can occur as sporadic isolated spots or as an overall effect.

**Probable causes:** Chemical breakdown of the binder, for example in alkyd and oleo resinous paints by reaction with alkali. Commonly seen when these types of paint are used on concrete or cement render.

#### 4.17.1.49 Settlement

**Description:** A term used to describe the settlement of pigment/solid in a liquid prior to application, occurring during paint storage. Settlement, which occurs after mixing and during application, can result in a variation in color in different areas.

**Probable causes:** Old stock, heavily pigmented paint, wrong formulation, or contamination of product. Can be a problem with zinc-rich primers.

#### 4.17.1.50 Solvent Lifting (also see [Wrinkling](#))

**Description:** Eruption of the surface of the paint film by wrinkling and blistering, which leads to a weak surface and ultimate coating breakdown.

**Probable causes:** Incompatible paint system used, topcoats with a strong solvent blend can attack underlying coatings with a weaker solvent blend, or overcoating before the previous coat has adequately hardened.

#### 4.17.1.51 Solvent Popping

**Description:** Solvent bubbles on the surface of the paint film soon after application.

**Probable causes:** Incorrect solvent blends, porous surfaces, or wrong environmental conditions.

#### 4.17.1.52 Tackiness

**Description:** Soft surface film of the applied coatings. Although, beyond the

wet and liquid stage, the paint film remains as a tacky and soft surface, sometimes only apparent on touching.

Probable causes:

There are various reasons why paint will remain tacky, including overthickness, addition of excessive thinners, incorrect, insufficient, or lack of curing agent, low drying/curing temperature, or the use of coating beyond its shelf life.

#### 4.17.1.53 Undercutting

**Description:** Corrosion beneath a paint film. Corrosion travels beneath the paint film and lifts the paint from the substrate, and in severe cases, can show as flaking, cracks, and exposed rust.

Probable causes:

The application of paint to a corroded substrate and/or rust creep from areas of mechanical damage and/or missing primer coats. Can be found in areas of poor design or access where inadequate preparation and coating thickness were applied and could also be due to a lack of maintenance.

#### 4.17.1.54 Water Spotting (also see [Rain Spotting](#))

**Description:** The spotty appearance of the paint film caused by drops of water on the surface, which remains after the water has evaporated. The effect may or may not be permanent.

Probable causes:

Rain drops falling on to a wet paint film, leaving permanent marks, or falling on a freshly dried but hard surface where after the water has evaporated, marks may be seen, which can be rubbed off.

#### 4.17.1.55 Wrinkling/Rivelling (also see [Crowsfooting](#))

**Description:** The development of wrinkling in the paint film during drying, appearing as wrinkling, swelling, and blistering of the coating.

Probable causes:

Usually due to the initial formation of a surface skin with solvent-based paints and related to shrinkage stress as the lower area of the film cures after the top surface. Can arise from overcoating before the previous coat has adequately hardened and swelling of the coating from reaction with solvent.

#### 4.17.1.56 Zinc Carbonates

**Description:** The loss of adhesion to galvanized surfaces and blistering of paint on a galvanized surface.

**Probable causes:**

White rust or carbonates on the surface of galvanizing prior to the application of the paint coating. Corrosion of zinc under the paint surface.

### 4.18.1 Historical Background

In recent years, it has been regarded as somewhat passé to refer to Sir Humphry Davy in a text on cathodic protection. However, his role in the application of cathodic protection should not be ignored. In 1824, Davy presented a series of papers to the Royal Society in London,<sup>1</sup> in which he described how zinc and iron anodes could be used to prevent the corrosion of copper sheathing on the wooden hulls of British naval vessels. His paper shows a considerable intuitive awareness of what are now accepted as the principles of cathodic protection. Several practical tests were made on vessels in harbor and on sea-going ships, including the effect of various current densities on the level of protection of the copper. Davy also considered the use of an impressed current

device based on a battery, but did not consider the method to be practicable.

The first ‘full-hull’ installation on a vessel in service was applied to the frigate HMS Samarang in 1824. Four groups of cast iron anodes were fitted, and virtually perfect protection of the copper was achieved. So effective was the system that the prevention of corrosion of the copper resulted in the loss of the copper ions required to act as a toxicide for marine growth, leading to increased marine fouling of the hull. Since this led to some loss of performance from the vessel, interest in cathodic protection waned. The beneficial action of the copper ions in preventing fouling was judged to be more important than preventing deterioration of the sheathing. Cathodic protection was therefore neglected for 100 years, after which it began to be used successfully by oil companies in the United States to protect underground pipelines.<sup>2</sup>

It is interesting that the first large-scale application of cathodic protection by Davy was directed at protecting copper rather than steel. It is also a measure of Davy’s grasp of the topic that he was able to consider the use of two techniques of cathodic protection, namely sacrificial anodes and impressed current, and two types of sacrificial anode, namely zinc and cast iron.

## 4.18.2 Electrochemical Principles

### 4.18.2.1 Aqueous Corrosion

The aqueous corrosion of iron under conditions of air access can be written as

The product, ferrous hydroxide, is commonly further oxidized to magnetite ( $\text{Fe}_3\text{O}_4$ ) or a hydrated ferric oxide ( $\text{FeOOH}$ ), that is, rust.

It is convenient to consider separately the metallic and nonmetallic reactions in eqn [1]:

To balance eqns [2] and [3] in terms of electrical charge, it has been necessary to add four electrons to the right-hand side of eqn [2] and to the left-hand side of eqn [3]. However, simple addition and rationalization of eqns [2] and [3] yield eqn [1].

We conclude that corrosion is a chemical reaction [1] occurring by an electrochemical mechanism (eqns [2] and [3]), that is, by a process involving electrical and chemical species. Figure 1 is a

schematic representation of aqueous corrosion occurring at a metal surface.

Equation [2], which involves consumption of the metal and release of electrons, is termed an anodic reaction. Equation [3], which represents consumption of electrons and dissolved species in the environment, is termed a cathodic reaction. Whenever spontaneous corrosion reactions occur, all the electrons released in the anodic reaction are consumed in the cathodic reaction; no excess or deficiency is found. Moreover, the metal normally takes up a more or less uniform electrode potential, often called the corrosion or mixed potential ( $E_{\text{corr}}$ ).

### 4.18.2.2 Cathodic Protection

It is possible to envisage what might happen if an electrical intervention was made in the corrosion reaction by considering the impact on the anodic and cathodic reactions. For example, if electrons were withdrawn from the metal surface, it might be anticipated that reaction [2] would speed up (to replace the lost electrons) and reaction [3] would slow down, because of the existing shortfall of electrons. It follows that the rate of metal consumption would increase.

By contrast, if additional electrons were introduced at the metal surface, the cathodic reaction would speed up (to consume the electrons) and the anodic reaction would be inhibited; metal dissolution would be slowed down. This is the basis of cathodic protection.

Figure 2 shows the effect on the corrosion reaction shown in Figure 1 of providing a limited supply of electrons to the surface. The rate of dissolution

**Figure 1** Schematic illustration of the corrosion of steel in an aerated environment. Note that the electrons released in the anodic reaction are consumed quantitatively in the cathodic reaction, and that the anodic and cathodic products may react to produce  $\text{Fe}(\text{OH})_2$ .

slows down because the external source rather than an iron atom provides two of the electrons. **Figure 3** shows the effect of a greater electron supply; corrosion ceases since the external source provides all the requisite electrons. It should be apparent that there is no reason why further electrons could not be supplied, when even more hydroxyl ( $\text{OH}^-$ ) ion would be produced, but without the possibility of a concomitant reduction in the rate of iron dissolution. Clearly, this would be a wasteful exercise.

The corrosion reaction may also be represented on a polarization diagram (**Figure 4**). The diagram

**Figure 2** Schematic illustration of partial cathodic protection of steel in an aerated environment. Note that one of the anodic reactions shown in **Figure 1** has been annihilated by providing two electrons from an external source; an excess of  $\text{OH}^-$  ions over  $\text{Fe}^{2+}$  now exists at the surface.

**Figure 3** Schematic illustration of full cathodic protection of steel in an aerated environment. Note that both anodic reactions shown in **Figure 1** have now been annihilated, and there is an accumulation of  $\text{OH}^-$  at the surface.

shows how the rates of the anodic and cathodic reactions (both expressed in terms of current flow  $I$ ) vary with electrode potential  $E$ . Thus, at  $E_a$ , the net rate of the anodic reaction is zero and it increases as the potential becomes more positive. At  $E_c$ , the net rate of the cathodic reaction is zero and it increases as the potential becomes more negative. (To be able to represent the anodic and cathodic reaction rates on the same axis, the modulus of the current has been drawn.) The two reaction rates are electrically equivalent at  $E_{\text{corr}}$ , the corrosion potential, and the corresponding current  $I_{\text{corr}}$  is an electrical representation of the rate of the anodic and cathodic reactions at that potential, that is, the spontaneous corrosion rate of the metal. That is, at  $E_{\text{corr}}$  the polarization diagram represents the situation referred to above; namely, that when spontaneous corrosion occurs, the rate of electron release equals the rate of electron consumption, and there is no net current flow although metal is consumed, and meanwhile the metal exerts a single electrode potential.

To hold the metal at any potential other than  $E_{\text{corr}}$  requires that electrons be supplied to, or be withdrawn from, the metal surface. For example, at  $E'$ , the cathodic reaction rate  $I'_c$  exceeds the anodic reaction rate  $I'_a$ , and the latter does not provide sufficient electrons to satisfy the former. If the metal is to be maintained at  $E'$ , the shortfall of electrons given by  $(|I'_c| - I'_a)$  must be supplied from an external source. This externally supplied current serves to reduce the metal dissolution rate from  $I_{\text{corr}}$  to  $I'_a$ .

At  $E_a$ , the net anodic reaction rate is zero (there is no metal dissolution) and a cathodic current equal to  $I''_c$  must be available from the external source to maintain the metal at this potential. It may also be apparent from **Figure 4** that, if the potential is maintained below  $E_a$ , the metal dissolution rate remains zero ( $I_a = 0$ ), but a cathodic current greater than  $I''_c$  must be supplied; more current is supplied without achieving a benefit in terms of metal loss. There will, however, be a higher interfacial hydroxyl ion concentration.

#### 4.18.2.3 Oxygen Reduction

In illustrating the corrosion reaction in eqn [1], the oxygen reduction reaction [3] has been taken as the cathodic process. Moreover, in **Figures 1–4**, oxygen reduction has been assumed. While there is a range of cathodic reactions that can provoke the corrosion of a metal (since to be a cathodic reactant, any particular species must simply act as an oxidizing

**Figure 4** Polarization diagram representing corrosion and cathodic protection. A corroding metal takes up the potential  $E_{\text{corr}}$  spontaneously and corrodes at a rate given by  $I_{\text{corr}}$ . If the potential is to be lowered to  $E'$ , a current equal to  $(|I'_c| - I'_a)$  must be supplied from an external source; the metal will then dissolve at a rate equal to  $I'_a$ .

agent to the metal), the most common cathodic reactant present in natural environments is oxygen. It is for this reason that the oxygen reduction reaction has been emphasized here.

When corrosion occurs, if the cathodic reactant is in plentiful supply, it can be shown both theoretically and practically that the cathodic kinetics are semilogarithmic, as shown in **Figure 4**. The rate of the cathodic reaction is governed by the rate at which electrical charge can be transferred at the metal surface. Such a process responds to changes in electrode potential, giving rise to the semilogarithmic behavior.

Because oxygen is not very soluble in aqueous solutions ( $\sim 10$  ppm in cool seawater, for example), it is not freely available at the metal surface. As a result, it is often easier to transfer electrical charge at the surface than for oxygen to reach the surface to take part in the charge transfer reaction. The cathodic reaction rate is then controlled by the rate of arrival of oxygen at the surface. This is often referred to as mass transfer control. Since oxygen is an uncharged species, its rate of arrival is unaffected by the prevailing electrical field and responds only to the local oxygen concentration gradient. If the cathodic reaction is driven so fast that the interfacial oxygen concentration is reduced to zero (i.e., the oxygen is consumed as soon as it reaches the surface), the oxygen concentration gradient to the surface reaches a maximum and the reaction rate attains a limiting value. Only an increase in oxygen concentration or an increase in flow velocity will permit an increase in the limiting value. The cathodic kinetics under mass transfer control will be as shown in **Figure 5**.

**Figure 5** Polarization diagram representing corrosion and cathodic protection when the cathodic process is under mass transfer control. The values of  $E_{\text{corr}}$  and  $I_{\text{corr}}$  are lower than when there is no mass transfer restriction, that is, when the cathodic kinetics follows the dotted line.

**Figure 5** demonstrates that, even when semilogarithmic cathodic kinetics is not observed, partial or total cathodic protection is possible. Indeed, **Figure 5** shows that the corrosion rate approximates to the limiting current for oxygen reduction ( $I_{\text{lim}}$ ), and the current required for protection is substantially lower than when semilogarithmic cathodic behavior prevails.

#### 4.18.2.4 Hydrogen Evolution

In principle, it is possible for water to act as a cathodic reactant with the formation of molecular hydrogen:

Indeed, in neutral solutions, the corrosion of iron with concomitant hydrogen evolution deriving from the reduction of water is thermodynamically feasible. In practice, this cathodic reaction is barely significant because the reduction of any oxygen present is both thermodynamically favored and kinetically easier. In the absence of oxygen, the hydrogen evolution reaction at the corrosion potential of iron is so sluggish that the corrosion rate of the iron is vanishingly small.

Nevertheless, hydrogen evolution is important in considering the cathodic protection of steel. Although hydrogen evolution takes little part in the corrosion of steel in aerated neutral solutions (see **Figure 6**), as the potential is lowered to achieve cathodic protection, it plays a larger, and eventually dominant, role in determining the total current demand. This too is demonstrated in **Figure 6** where, it must be remembered, the current supplied from the external source at any potential must be sufficient to sustain the total cathodic reaction, that is, both oxygen reduction and hydrogen evolution reactions at that potential. It will be seen that to lower the potential much below  $E_a$  entails a substantial increase in current and significantly more hydrogen evolution.

### 4.18.3 Methods of Applying Cathodic Protection

There are two principal methods of applying cathodic protection, namely the impressed current technique and the use of sacrificial anodes.

**Figure 6** Polarization diagram showing the limited role hydrogen evolution plays at the corrosion potential of steel in aerated neutral solution, the larger role in determining cathodic protection currents, and the dominant role in contributing to current requirements at very negative potentials. The dotted line shows the total cathodic current due to oxygen reduction and hydrogen evolution.

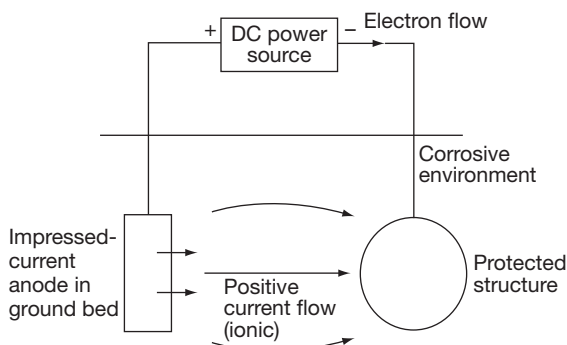

The former includes the structure as part of a driven electrochemical cell, and the latter includes the structure as part of a spontaneous galvanic cell.

#### 4.18.3.1 Impressed Current Method

**Figure 7** illustrates the use of an external power supply to provide the cathodic polarization of the structure. The circuit comprises the power source, an auxiliary or impressed current electrode, the corrosive solution, and the structure to be protected. The power source drives a positive current from the impressed current electrode through the corrosive solution and onto the structure. The structure is thereby cathodically polarized (its potential is lowered), and the positive current returns through the circuit to the power supply. Thus, to achieve cathodic protection, the impressed current electrode and the structure must be in both electrolytic and electronic contact.

The power supply is usually a transformer/rectifier that converts AC power to DC. Typically, the DC output will be in the range 15–100 V and 5–100 A, although 200 V/200 A units are not unknown. Thus, fairly substantial driving voltages and currents are available. Where mains power is not available, diesel or gas engines, solar panels, or thermoelectric generators have all been used to provide suitable DC.

It will be seen that the impressed current electrode discharges positive current, that is, it acts as an anode in the cell. There are three generic types of anode used in cathodic protection, namely consumable, nonconsumable, and semiconsumable. The consumable electrodes undergo an anodic reaction that involves their consumption. Thus, an anode made of scrap iron produces positive current by the reaction

**Figure 7** Schematic diagram of cathodic protection using the impressed-current technique.

The ferrous ions then enter the environment as a positive current carrier (although in practice the current will be carried in the environment by aqueous ions such as  $\text{Na}^+$  and  $\text{Cl}^-$ ). Since the dissolving anode must obey Faraday's law, it follows that the wasting of the anode will be proportional to the total current delivered. In practice, the loss for an iron anode is approximately  $9 \text{ kg A}^{-1} \text{ year}^{-1}$ . Thus, consumable anodes must be replaced at intervals, or be of sufficient size to remain as a current source for the design life of the protected structure. This poses some problems in design because, as the anode dissolves, the resistance it presents to the circuit increases. More important, it is difficult to ensure continuous electrical connection to the dissolving anode.

Nonconsumable anodes sustain an anodic reaction that decomposes the aqueous environment rather than dissolves the anode metal. In aqueous solutions the reaction may be

or in the presence of chloride ions

Anodes made from platinized titanium or niobium belong to this category.

Because these anodes are not consumed faradaically, they should not, in principle, require replacement during the life of the structure. However, to remain intact, they must be chemically resistant to their anodic products (acid and chlorine) and, where the products are gaseous, conditions must be produced that allow the gas to escape and not interfere with anode operation. This is particularly true of the platinized electrodes because they can operate at high current density ( $>100 \text{ A m}^{-2}$ ) without detriment, but will then produce high levels of acidity ( $\text{pH} < 2$ ) and large volumes of gas. Ground-bed design (the way in which the anode is installed) is therefore crucial.

Although the anodes are described as non-consumable, they do suffer some loss of the thin ( $\sim 2.5\text{--}10 \text{ mg m}^{-3}$ ) platinized coating. This loss, which unfortunately has become known as the wear rate although there is no question of the loss being due to mechanical wear, is usually small, related to the total current passed, and increased if the applied current has an AC component. Typically, values for the loss rate are  $8 \text{ mg A}^{-1} \text{ year}^{-1}$  for platinized titanium, which may be increased 10-fold if an AC component of  $<100 \text{ Hz}$  is present. Negative-going current spikes, such as may be induced by a poorly designed thyristor switching

device, even given otherwise clean DC, can produce a 100-fold increase in the rate of loss.

The semiconsumable electrodes, as the name implies, suffer rather less dissolution than Faraday's law would predict and substantially more than the nonconsumable electrodes. This is because the anodic reaction is shared between oxidizing the anode material (causing consumption) and oxidizing the environment (with no concomitant loss of metal). Electrodes made from silicon-iron, chromium-silicon-iron and graphite fall into this category.

**Table 1** gives a brief summary of the behavior of some impressed current anodes, and protection by impressed current is discussed in more detail elsewhere.

#### 4.18.3.2 Sacrificial Anodes

Using the impressed-current technique, the driving voltage for the protective current comes from a DC power source. The sacrificial anode technique uses the natural potential difference that exists between the structure and a second metal in the same environment to provide the driving voltage. No power source is employed. Moreover, the dissolution of the second metal, that is, the sacrificial anode, provides the source of electrons for cathodic polarization of the structure. Thus, while the impressed-current anode may be more noble or more base than the protected structure because the power source forces it to act as an anode, the sacrificial anode must be spontaneously anodic to the structure, that is, be more negative in the galvanic series for the given environment. Thus, in principle, zinc, aluminum, or magnesium could be used to protect steel, and iron to protect copper. **Figure 8** illustrates the use of a sacrificial anode for cathodic protection.

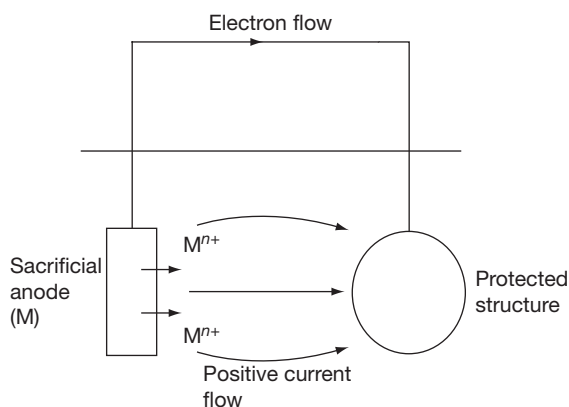

In practice, pure metals are never used as sacrificial anodes. There are a variety of reasons for this, which includes the need for

1. a reliable, reproducible and negative operating potential for the anode;
2. a high and reproducible capacity ( $\text{A h kg}^{-1}$ ) for the anode;
3. uniform dissolution of the anode so that all metal is consumed usefully in providing cathodic protection and not wastefully by mechanical loss;
4. freedom from any loss of activity by the anode due to passivation.

For these reasons, alloying elements appear in all the commercial anodes, and very careful quality control

**Table 1** Impressed-current anode materials

Material	Consumption rate or operating current density	Notes
Consumable:		
Scrap iron	$\sim 9 \text{ kg A}^{-1} \text{ year}^{-1}$	Cheap: suitable for buried or immersed use
Cast iron	$< 9 \text{ kg A}^{-1} \text{ year}^{-1}$	Cheap; buried or immersed use; carbon skeleton reduces consumption
Semiconsumable:		
Silicon cast iron (Fe-14Si-(3 Mo)	$5\text{--}50 \text{ A m}^{-2}$ (in freshwater or soil)	Buried or immersed use; consumption ( $< 1 \text{ kg A}^{-1} \text{ year}^{-1}$ ); Mo reduces consumption in seawater
Graphite	$2.5\text{--}10 \text{ A m}^{-2}$	Consumption rate very much less than steel or cast iron ( $< 1 \text{ kg A}^{-1} \text{ year}^{-1}$ ); chloride ions reduce consumption
Nonconsumable:		
Lead alloys:		
1. Pb-6Sb-1Ag	$< 50\text{--}200 \text{ A m}^{-2}$ (in seawater)	PbO <sub>2</sub> film restrains consumption
2. Pt-activated	$< 50\text{--}500 \text{ A m}^{-2}$ (in seawater)	PbO <sub>2</sub> film protective

is required to keep disadvantageous tramp elements (notably iron and copper) below defined threshold levels. Many anode failures can be attributed to poor production quality control. A guide to minimum quality standards has been produced.<sup>3</sup>

**Table 2** gives electrochemical properties for various generic anode types. It will be apparent that the driving voltages that are available from sacrificial anodes are substantially less than those available from power sources. At best, an anode will produce 1 V to steel, whereas an impressed current power source may produce up to 100 V.

A more detailed treatment of cathodic protection by sacrificial anodes is provided elsewhere in this book.

## 4.18.4 Proof of Protection

### 4.18.4.1 Steel

**Figure 4** demonstrates that the rate of dissolution of iron (or any other metal) decreases as the potential is made more negative. **Figure 6** shows that the current required to reach any given potential below the corrosion potential ( $E_{\text{corr}}$ ) will vary according to the composition of the corrosive solution. Thus **Figure 6** shows that, in the absence of oxygen, the current requirement would be low, but would increase to a value approximating to the limiting current in its presence. Moreover, since the limiting current can be increased by increasing the oxygen concentration or the solution flow rate, the current required for protection will change predictably with change in either of these parameters.<sup>4</sup> It follows that the current required to prevent corrosion completely (i.e., in principle to achieve  $E_a$ ) will vary according to the environment and the environmental dynamics. As a consequence, there is no single current that will assure protection in all cases. Current supplied is not, therefore, an unequivocal indication of the effectiveness of protection.

By contrast, it appears from **Figures 4 and 6** that a potential measurement would be more reliable: specifically, that  $E_a$  (the equilibrium potential for the

**Table 2** Typical sacrificial anode compositions and operating parameters

Alloy	Environment	Operating voltage vs. Ag/AgCl/seawater (V)	Driving voltage <sup>a</sup> (V)	Capacity (Ah/kg)

It is often important to control impurities and especially Fe, Cu, Ni, and Si, although a controlled Si content is essential to some aluminum alloys.

<sup>a</sup>The driving voltage to bare steel, that is, protection potential of steel-anode operating potential.

<sup>b</sup>US Military Specification.

iron/ferrous-ion electrode given a suitably low ferrous ion concentration) would always represent the achievement of full protection for iron.

Almost without exception, all the accepted criteria for full cathodic protection of iron are based on a potential measurement. The various recommended practices published by the U.S. National Association of Corrosion Engineers (NACE) give six criteria for full protection.<sup>5-11</sup> The current British Standard Code of Practice<sup>12</sup> gives one. These are summarized in **Table 3**. Only the first three are useful; the remaining ones are of dubious value or expressions of pious hope.

The most widely accepted criterion for protection of steel at room temperature (the protection potential) in aerobic conditions is -0.85 V with respect to a Cu/CuSO<sub>4</sub> reference electrode. In anaerobic conditions, -0.95 V (versus Cu/CuSO<sub>4</sub>) is the preferred protection potential because of the possible presence of active sulfate-reducing bacteria (SRB).

Various limitations on the most negative potential that may be imposed during cathodic protection are often quoted for high-strength steels (typically -1.0 V versus Cu/CuSO<sub>4</sub> for steels in the 700-800 MPa tensile strength range). The restriction is to limit the evolution of hydrogen at the structure and thereby prevent hydrogen absorption with the possibility of embrittlement of the steel, possibly leading to fracture. The consequence is that the useful window of potential in which the steel can operate is severely restricted, especially under anaerobic conditions.

It must not be assumed that the protection potential is numerically equal to the equilibrium potential for the iron/ferrous-ion electrode ( $E_a$ ). The standard equilibrium potential ( $E^\circ$ ) for the iron/ferrous-ion is -0.440 V (versus the standard hydrogen electrode).

**Table 3** Cathodic protection criteria: after British Standard Code of Practice<sup>12</sup> and NACE Recommended Practices<sup>5-11</sup>

1.  $\leq -0.85$  V w.r.t Cu/CuSO<sub>4</sub> with current applied but minimizing  $IR$  error
2. Negative shift  $\geq 300$  mV when current applied
3. Positive shift  $\geq 100$  mV when current interrupted
4. More negative than beginning of Tafel segment of cathodic polarisation ( $E - \log i$ ) curve
5. A net protective current in the structure at former anodic points
6. Polarize all cathodic areas to open circuit potential of most active anode areas

If the interfacial ferrous ion concentration when corrosion ceases is approximately  $10^{-6}$  M, then according to the Nernst equation, the equilibrium potential ( $E_a$ ) is given by

$$E_a = E^\circ + \frac{2.303}{2F} RT \log(a_{\text{Fe}^{2+}})$$

where  $a_{\text{Fe}^{2+}}$  is the activity or thermodynamic concentration of the ferrous cation,  $R$  is the gas constant,  $F$  is Faraday's constant, and 2 represents the number of units of charge transferred (i.e., the doubly charged ferrous ion). Thus,  $E_a = -0.62$  V versus the standard hydrogen electrode or -0.93 V versus Cu/CuSO<sub>4</sub>. This is a value substantially more negative than the accepted protection potential (-0.85 V).

A simple calculation based on the solubility product of ferrous hydroxide and assuming an interfacial pH of 9 (due to the alkalization of the cathodic surface by reaction [3]) shows that, according to the Nernst equation, at -0.85 V (versus Cu/CuSO<sub>4</sub>), the ferrous ion concentration then present is sufficient to permit deposition of the hydroxide ion. It appears that the ferrous hydroxide formed may be protective,

and that the practical protection potential ( $-0.85$  V), as opposed to the theoretical protection potential ( $E_a = -0.93$  V), is governed by the thermodynamics of precipitation and not those of dissolution.

It is also worth noting that the exact achievement of the so-called protection potential is not essential to excellent corrosion control. **Figures 4–6** show the anodic kinetics as semilogarithmic in character. Behavior approaching this is observed in practice for steel in many environments. Thus, the first increment of negative potential shift will reduce the anodic dissolution rate substantially. A second equal shift will be 10 times less effective and will require the application of very much more current. A third equal shift will be 10 times less effective again. That is, the dissolution rate decreases asymptotically as the full protection potential is approached; a small shortfall in cathodic polarization is not, therefore, disastrous. By contrast, the current required to achieve the protection potential, and more particularly to exceed it, is often very substantial and may increase exponentially. There may often be good economic reasons for permitting a minor shortfall of polarization.

#### 4.18.4.2 Other Metals

In principle, all metals may be protected by cathodic protection. In practice, it is not always relevant, either because the metals are, to all intents and purposes, naturally immune to corrosion (the noble metals) and often not used as engineering materials or, being base metals, they are well protected by the spontaneous formation of a passive film in aqueous solution (aluminum or a stainless steel, for example).

Copper-base alloys will corrode in aerated conditions. It is, therefore, sometimes appropriate to consider cathodic protection. It becomes particularly relevant when the flow rates are high or when the design of an item causes the copper to be an anode in a galvanic cell (e.g., a copper alloy tube plate in a titanium-tubed heat exchanger). Corrosion can be controlled by polarization to approximately  $-0.6$  V (versus Cu/CuSO<sub>4</sub>) and may be achieved using soft-iron sacrificial anodes.

Some metals are amphoteric: that is, they form simple cations (in acid solutions) and soluble oxyanions (in alkaline solution); only in the mid-pH range is a protective film stable. Since cathodic protection produces alkali at the structure's surface, it is important to restrict the polarization, and thereby the amount of hydroxyl ion produced, in these cases. Thus both lead and aluminum will suffer cathodic

corrosion under cathodic protection if the potential is made excessively electronegative.

Many passive metals suffer pitting attack when aggressive ions (usually chloride) enter the system. It is possible to forestall pitting, or to stop it once started, using cathodic protection. It is not necessary to polarize to the protection potential of the metal; a negative shift of 100 mV from the natural corrosion potential in the environment will often be sufficient. This technique has been applied to various stainless steels and to aluminum.<sup>13</sup> The philosophy is not unlike that applied to rebar in concrete.

Where there is a perceived risk of crevice corrosion, cathodic protection can often be used to prevent its initiation. Once more, a 100-mV cathodic polarization will usually prove sufficient. However, it is doubtful whether cathodic protection can arrest crevice corrosion once started and, despite claims to the contrary, whether it could be effective in arresting stress-corrosion cracking. The problem lies in the fundamental difficulty of forcing cathodic current into an occluded area.

Some recommended protection potentials for other metals are given in **Table 4**.

#### 4.18.4.3 Steel in Concrete

Concrete is a very benign environment for steel so long as its natural pH remains high and no aggressive species enters. The low corrosion rate experienced by the steel is due to the formation of a protective passive film. There are a number of circumstances that allow chloride ions to enter reinforced concrete. When these ions reach the reinforcing bar (rebar), they may cause localized corrosion damage to it, with consequent cracking or even spalling of the concrete. The result is both unsightly and potentially dangerous. Impressed-current cathodic protection has been used to overcome the problem, and significant beneficial effects have been claimed.<sup>14–16</sup>

The proof of protection is more difficult to establish in this case for two reasons. First, the object is to

**Table 4** Recommended protection potentials for other metals<sup>12</sup>

<i>Metal</i>	<i>Protection potential (V vs. Cu/CuSO<sub>4</sub>)</i>
Lead	$-0.6$
Copper-base alloys	$-0.5$ to $-0.65$
Aluminum	
Positive limit	$-0.95$
Negative limit	$-1.2$

restore passivity to the rebar and not to render it virtually immune to corrosion. Second, it is difficult to measure the true electrode potential of rebars under these conditions. This is because the cathodic-protection current flowing through the concrete produces a voltage error in the measurements made (see below). For this reason, it has been found convenient to use a potential decay technique to assess protection rather than a direct potential measurement. Thus, a 100-mV decay of polarization in 24 h once current has been interrupted has been adopted as the criterion for adequate protection.<sup>17</sup> It will be seen that this proposal does not differ substantially from the decay criterion included in **Table 3** and recommended by NACE for assessing the full protection of steel in other environments. Of course, in this case, the cathodic polarization is intended to inhibit pit growth and restore passivity, not to establish effective immunity.

#### 4.18.4.4 Potential Measurements

It is clear that to ensure adequate protection of a structure under cathodic protection, it is necessary to measure its electrode potential. This can be achieved only by using a reference electrode placed in the same environment as the structure and measuring the emf of the cell so formed. Since the electrode potentials of different types of reference electrode vary, it is clear that the measured emf will also vary according to the particular reference electrode used. It follows that the potential measured must always be recorded with respect to the reference electrode deployed, which must always be stated.

The protection potential for a given metal is numerically different according to the reference electrode used. Thus the protection potential for iron in aerobic environments is

- −0.85 V versus Cu/CuSO<sub>4</sub>;
- −0.80 V versus Ag/AgCl/seawater;
- −0.77 V versus Ag/AgCl/1 M KCl;
- −0.84 V versus Ag/AgCl/0.1 M KCl;
- −0.55 V versus standard hydrogen electrode.

It is fundamental that a reference electrode should have a stable and reproducible potential. Not all reference electrodes are suitable for all environments or circumstances. For example, a Cu/CuSO<sub>4</sub> electrode is suitable for use in soil, but should never be used in seawater or on concrete. Contamination of the electrode can occur, which will produce serious changes in the reference potential.

The Ag/AgCl/seawater electrode should be used only in seawater since the electrode is merely

a Ag/AgCl element that provides a known stable reference potential when immersed in clean seawater. Immersion in any other chloride-containing fluid will produce a different reference potential depending on the chloride concentration present in the environment. Only if appropriate allowance is made for the particular chloride content present, will the potentials measured be reliable. Commercial Ag/AgCl electrodes are available in which the element is encapsulated within an environment containing a fixed chloride content. The electrodes are very stable and suitable for short-term use in fluids containing any concentration of chloride or no chloride ions at all. They are not suitable for continuous immersion in fluids in which the chloride concentration of the encapsulation will change with time as a result of chloride leaching (e.g., in distilled water) or chloride ion ingress (e.g., in seawater).

Finally, calomel electrodes (and particularly hydrogen electrodes) are not suitable for field measurements because they are not sufficiently robust. The calomel electrodes are, however, essential for calibrating the field reference electrodes. Saturated KCl calomel electrodes are the most suitable because there is then no doubt about the reference potential of the calibrating electrode. Lack of adequate calibration is a common cause of cathodic protection system mismanagement.

Incorrect potential measurement technique leads to another management problem. If the potential of a freely corroding metal is measured, the values recorded will remain constant wherever the reference electrode is placed in the environment. If the same metal is under cathodic protection, the positioning of the reference electrode is crucial. This is because the cathodic protection current flowing through the corrosive environment produces an electric field gradient as the current  $I$  flows through the environment of resistance  $R$ . Thus, when the reference electrode is placed remote from the metal surface, the measured potential comprises the true electrode potential of the metal and the potential difference in the environment between the metal and the reference electrode due to the electric field. As the reference electrode is moved closer to the metal surface, less of the electric field is included in the measurement and the potential of the metal appears more positive (**Figure 9**). That is, with current flowing, a remote reference electrode ensures measurement of a more negative potential for the metal (it appears better protected than it is), while the closer the reference electrode is placed to the

**Figure 9** Diagram illustrating the source of the  $IR$  error in potential measurements on a cathodically protected structure. BA is the absolute electrode potential of the structure; CD is the absolute electrode potential of the anode; and CB is the field gradient in the environment due to cathodic protection current flux. A reference electrode placed at E will produce an  $IR$  error of EF in the potential measurement of the structure potential. If placed at G, the error will be reduced to GH. At B there would be no error, but the point is too close to the structure to permit insertion of a reference electrode. If the current is interrupted, the field immediately becomes as shown by the dotted line, and no  $IR$  is included.

metal, the more positive, and more reliable, the measurement becomes.

The deviation from the correct potential value by inclusion of the field gradient in the measurement is often called the  $IR$  error, and it must be minimized in assessing the state of polarization of a cathodically protected structure. The recommended protection potentials all assume no significant  $IR$  error in the measurement.

It is desirable to measure the potential of a structure without an  $IR$  error. It is not always possible to place the reference electrode close to the structure to minimize the  $IR$  error but it can be achieved using the so-called instant-off technique. The technique relies on the fact that when the current is interrupted, the  $IR$  effect, being ohmic, dissipates immediately but the polarization decays much more slowly. Thus, if the current is switched off and the potential is measured immediately, the  $IR$ -free polarized potential of the structure can be measured. Where the cathodic protection system uses multiple power sources, it is necessary to switch off all the units simultaneously if true  $IR$ -free conditions are to be achieved.

In an impressed-current cathodic protection system, the power source has a substantial capacity to deliver current and it is possible to change the state of polarization of the structure by altering that current.

Thus, effective control of the system depends on credible potential measurements. Since the current output from any given anode is substantial, the possibility of an  $IR$  error, which may reach many hundreds of millivolts in any potential measurements made, is high. Thus the instant-off technique (or some other means of avoiding  $IR$  error) is essential to effective system management.

By contrast, a cathodic protection system based on sacrificial anodes is designed from the outset to achieve the required protection potential. If this is not achieved in practice, there is no control function that can be exercised to improve the situation. Some remodeling of the system will be required. Moreover, the current from each current source (the sacrificial anodes) is modest so that field gradients in the environment are not significant. It is at once clear that potential measurements are less significant in this case and instant-off measurements are neither necessary nor possible.

#### 4.18.5 Current Requirements

It was indicated earlier that the cathodic current is a poor indicator of adequate protection. While, to a first approximation, the protection potential is a function of the metal, the current required for protection is a function of the environment and, more particularly, of the cathodic kinetics it entails. From **Figure 4**, it is apparent that any circumstance that causes the cathodic kinetics to increase will cause both the corrosion rate and the current required for full ( $I''_c$ ) or partial ( $|I'_c| - I'_a$ ) protection to rise. For example, an increase in the limiting current in **Figure 5** produced by an increase in environmental oxygen concentration or in fluid flow rate will increase the corrosion rate and the cathodic protection current. Similarly, if the environment is made more acidic, the hydrogen evolution reaction is more likely to be involved in the corrosion reaction and it also becomes easier and faster; this too produces an increased corrosion rate and cathodic current demand.

In short, the current demand for cathodic protection varies according to the aggressiveness of the corrosive environment. It is for this reason that cathodic protection finds its greatest application where the pH is close to neutral. The more acidic environments entail a current output that rapidly becomes uneconomical. The more alkaline environments prove less aggressive to the structure and therefore often do not justify cathodic protection.

#### 4.18.6 Coatings and Cathodic Protection

Coatings (e.g., paints) applied to metal surfaces can be extremely effective in containing the corrosion of the substrate in many environments. This is particularly true for steel in natural environments. However, no freshly applied coating is entirely free from defects and so there will always be small areas which are exposed directly to the corrosive environment. It is possible to reduce, but not eliminate, these defects by paying attention to workmanship. In practice, it becomes increasingly expensive to achieve fewer and fewer defects because of the need for high-grade inspection as well as the detection and repair of individual defects.

Large structures, even in near-neutral pH environments, require a considerable current for cathodic protection. As a result, structure coatings are an almost mandatory requirement when cathodic protection is contemplated. The coating then provides the major part of the protection, and the cathodic protection provides the protection at the coating defects. This apparently ideally complementary behavior occurs because the coating defects represent a low resistance path, and therefore a preferred route, to the structure, for the cathodic protection current. It is now apparent that the coating does not need to achieve total surface coverage and the cathodic protection system must deliver only a fraction (often less than 1%) of the current that would be required to protect a bare structure. **Figure 10** shows

**Figure 10** Schematic diagram illustrating the economic benefit of the conjoint use of coating and cathodic protection. The increasing cost of coating as the coating is made progressively more defect free is shown; the corresponding cost of applying cathodic protection to the holidays decreases. The dotted line shows the total cost, and that there is overall benefit in using a good coating reinforced by cathodic protection.

schematically that there is an optimum combination of coating quality and cathodic protection that minimizes the cost of protecting a structure.

A coating deteriorates chemically and mechanically during its lifetime. This leads to a progressive increase in both the number of defects and the current required to protect the steel as they occur. Fortunately, each new defect represents a new low-resistance path and the cathodic protection current will flow to it to provide protection. Of course, this means that the cathodic protection system as installed must have sufficient reserve to provide this necessary extra current. This is readily accommodated in an impressed-current system where, if correctly designed, the voltage output can be increased to provide the requisite current. It is rather more difficult in the case of a sacrificial anode system because, as the anodes get smaller (by dissolving sacrificially), they are not capable of delivering more current. Thus increasing current demand develops alongside decreasing current availability. Of course, it is possible to provide anodes capable of delivering substantially more current initially in order to be able to provide sufficient current for later demand. This entails anodes operating in their early life at low current densities, which has sometimes been known to result in anode passivation and failure to deliver any significant current when it is needed.

Notwithstanding this latter difficulty, cathodic protection is usually applied to coated structures. Thus, ships, many piers and jetties, and virtually all buried pipelines are coated when cathodic protection is applied. Liquid storage tanks standing on sand or bitumen sand often have the underside of their base plate under cathodic protection. Here coating is often omitted, but this is more often due to ignorance of the designer than a conscious decision not to coat. Only offshore oil production platforms, particularly in the North Sea, are cathodically protected but often deliberately uncoated. There are two reasons for this. First, these structures are almost all protected using sacrificial anodes and it is easier to design for a more or less constant current demand than for an increasing current demand in these systems. Second, the construction of the platforms is made against a tight schedule; any weather conditions that prevented completion of coating would involve launching a platform with an incomplete coating and insufficient anodes to protect the now partially coated structure. It is certainly true that the first platforms in the North Sea were coated and cathodically protected. However, at that time the only reliable marine anodes

were based on zinc alloys which entailed a heavy weight penalty (because they have a low capacity) and there was thus a pressing need to reduce anode weight by coating.

#### 4.18.7 Calcareous Deposit

It has been noted that the total current required to protect large structures can be substantial even in mildly corrosive environments. In seawater, for example, an initial current in the region of  $200 \text{ mA m}^{-2}$  for bare steel might well be required in the North Sea. This is because the relatively high oxygen concentration and the tide and wave action all contribute to a facile cathodic reaction. Fortunately, this current diminishes with time. The reason for this is the protective scale on the steel surface, which forms during cathodic protection by decomposition of the seawater.

During cathodic protection, the dissolved oxygen is reduced to produce hydroxyl ions:

causing an increase in the pH at the interface. Seawater contains carbonate and bicarbonate ions that are in a pH-dependent equilibrium with one another:

The higher the pH of the seawater, the greater will be the proportion of carbonate ions present (since as the pH increases, so the  $\text{H}^+$  concentration decreases, thereby moving the equilibrium to the right). It follows that at a surface under cathodic protection, the hydroxyl ion produced has the effect of increasing the local carbonate ion concentration.

Seawater also contains calcium ions which form an insoluble carbonate with carbonate ions:

An increase in carbonate-ion concentration moves the equilibrium in favor of calcium carbonate deposition. Thus, one secondary effect of cathodic protection in seawater is the production of  $\text{OH}^-$ , which favors the production of  $\text{CO}_3^{2-}$ , which in turn promotes the deposition of  $\text{CaCO}_3$ . Cathodically protected surfaces in seawater will often develop an aragonite ( $\text{CaCO}_3$ ) film. This film is commonly referred to as a calcareous deposit.

Similarly, the seawater contains magnesium ions which can react with the hydroxyl ion directly to

form magnesium hydroxide:

Thus, brucite,  $\text{Mg}(\text{OH})_2$ , is also commonly found on surfaces under cathodic protection in seawater. Because more hydroxyl ions (higher pH) are required to cause magnesium hydroxide to precipitate, the magnesium is virtually always found in the calcareous deposits associated with calcium.<sup>18</sup>

The practical consequences of these events are that, once the calcareous film has formed, a cathodic current density at least an order of magnitude lower than that required to protect bare steel is needed to maintain protection. Although temporary damage to the film (e.g., storm action) may create a temporarily increased current demand, the film soon repairs and the lower current demand is restored. There is, however, a danger in excessive cathodic polarization: hydrogen is evolved at the steel surface, which, as it emerges, can itself disrupt the film mechanically. Since hydrogen continues to be produced so long as there is excessive polarization, there is continuing mechanical damage to the film and a more or less permanent increase in the cathodic current required for protection.

On the basis of laboratory experiments, it is widely believed, but there is little field evidence to prove, that high initial cathodic current densities promote the development of thinner, more compact, and more protective calcareous deposits. If this could be proved, some reduction in the sacrificial anode burden on a structure might be possible. As a result, some attention has been paid to the possibility of designing cathodic protection systems capable of delivering a high initial current with a view to reducing the total lifetime current required to attain and maintain protection. In general, this approach has involved proposals to use a limited number of high-current-output magnesium alloy sacrificial anodes to reinforce the anode burden (usually aluminum alloy) installed to provide long-term protection. It remains to be seen whether this is, or could be, successful.

#### 4.18.8 Potential Attenuation in Impressed-Current Systems

An impressed-current cathodic protection system circuit comprises an anode, the power source, the structure, and the environment in which it is placed. In addition, there are electrical connections between the power source and the anode and between the

power source and the structure (at the so-called negative drain point). The voltage available from the power source is used to polarize the anode and the structure and to overcome the electrical resistance of the environment and the metallic circuit, including that of the structure itself. It follows that the overall circuit resistance to various parts of a very large structure will differ and, where the resistance is higher, the voltage available for polarization of the structure will be lower. Thus, on large structures protected by a limited number of anodes, some lateral variation in the level of polarization is to be expected. This variation of potential is referred to as attenuation. Given that to ensure full protection the structure should everywhere be polarized at least to the protection potential, some part of it must be polarized to a greater extent. We have seen that more polarization requires more cathodic current. In the interest of economy, it is important to minimize attenuation as far as possible. One practical way to achieve this is to use a protective coating and thus limit the total current in the circuit. It may then still prove desirable to use more than one anode grounded to render the attenuation less extreme. To pursue this latter course, it is helpful to have some assessment of the likely level of attenuation that will be experienced on a given structure.

No exact mathematical analysis of potential attenuation for all structures has yet been developed. Some indicative analysis has been achieved for a buried pipeline,<sup>19</sup> which is perhaps the simplest case.

In making the analysis, it is assumed that the anode grounded is remote from the pipeline. That is, the length of the pipeline in question stands in what is virtually a uniform anode field, as shown in **Figure 11**. Since the electrical potential on the soil

**Figure 11** Schematic diagram showing an impressed-current anode installed in a groundbed remote from a pipeline. The positive current produces a field gradient in the soil, but the gradient tends to zero close to the line, producing a uniform lateral electrical potential on the soil side.

side is constant, any electrical potential change in the pipeline metal due to current flow within it reflects an equal electrode potential change at the pipe-soil interface. The change is also numerically equal to the cathodic overpotential, that is, the shift in electrode potential from the spontaneous corrosion potential.

We assume that the current enters the pipeline from the soil side through defects in the coating and returns to the power source via the line and one of the drain points, as shown in **Figure 12**. If the total current in the pipeline at a point a distance  $x$  from a drain point is  $I_x$ , then the change in current per unit length at  $x$  is the current entering at  $x$ :

$$\frac{dI_x}{dx} = -2\pi r i_x \quad [5]$$

where  $r$  is the radius of the pipeline and  $i_x$  is the current density entering at  $x$ .

The electrical potential change along the pipeline at  $x$  is

$$\frac{d\phi_x}{dx} = -R_L I_x$$

where  $\phi_x$  is the electrical potential at  $x$  and  $R_L$  the resistance of the metallic pipeline/unit length. However, since the rate of electrical potential change is equal to the rate of change of overpotential, given a remote grounded, it follows that

$$\frac{d\eta_x}{dx} = -R_L I_x \quad [6]$$

where  $\eta_x$  is the overpotential and is the difference between the actual potential at  $x$  and the free corrosion potential of the metal.

From eqns [5] and [6]:

$$\frac{d^2\eta_x}{dx^2} = R_L (2\pi r i_x) \quad [7]$$

**Figure 12** Schematic representation of a pipewall subject to cathodic protection (see text).  $\eta_x$  = overpotential at  $x$ ;  $\eta_a$  = overpotential at  $x = 0$ ;  $\eta_{prot}$  = overpotential at  $x = a/2$ ;  $I_x$  = current line at  $x$ ;  $i_x$  = current density entering line at  $x$ ;  $I_a$  = current in line at  $x = 0$  from one side of drain point ( $2I_a$  = total current drain);  $a$  = distance between the drain points.

Now, when  $i_x$  is small, the polarization of the pipeline is approximately directly proportional to the true current density ( $i'_x$ ) at the holidays in the coating. Thus

$$\eta_x = k' i'_x \quad [8]$$

Also,

$$i'_x = \frac{i_x}{f}$$

where  $f$  is the fraction of the surface covered by holidays in the coating and is inversely proportional to the resistance of the coating/unit area ( $z$ ).

Thus

$$\eta_x = k' i'_x = \frac{k' i_x}{f} = K i_x z \quad [9]$$

where  $K$  is a constant that depends on the nature of the structure to be protected and the properties of the soil.

From eqns [7] and [9]:

$$\frac{d^2 \eta_x}{dx^2} = R_L \left( \frac{2\pi r}{Kz} \right) \eta_x \quad [10]$$

The solution to eqn [10] for an infinite pipeline, that is, when  $\eta_x = 0$ ,  $x = \infty$  and when  $\eta_x = \eta_a$ ,  $x = 0$ , is

$$\eta_x = \eta_a \exp \left[ - \left[ \frac{2\pi r R_L}{Kz} \right]^{1/2} x \right] \quad [11]$$

However, if the pipeline has multiple drain points separated by distance  $a$ , and the aim is that the pipeline electrode potential should just reach the protection potential at the mid-point ( $x = a/2$ ), then  $\eta_x = a/2$  is equal to  $\eta_{prot}$  (the overpotential required just to achieve the protection potential). At  $x = a/2$ , the current in the line is zero and  $(d\eta_x/dx)_x = a/2$  is also zero. Thus

$$\eta_x = \eta_{prot} \cosh \left[ \left[ \frac{2\pi r R_L}{Kz} \right]^{1/2} \left[ x - \frac{a}{2} \right] \right] \quad [12]$$

and

$$\eta_x = \eta_{prot} \cosh \left[ - \left[ \frac{2\pi r R_L}{Kz} \right]^{1/2} \frac{a}{2} \right] \quad [12a]$$

The current in an infinite pipeline is obtained by differentiating eqn [11] and substituting into eqn [6]:

$$I_x = \left[ \frac{2\pi r R_L}{Kz} \right]^{1/2} \frac{\eta_a}{R_L} \exp \left[ - \left[ \frac{2\pi r R_L}{Kz} \right]^{1/2} x \right] \quad [13]$$

The drainage current (i.e.,  $2I_x = 0$ ) is therefore

$$2 \left[ \frac{2\pi r R_L}{Kz} \right]^{1/2} \frac{\eta_a}{R_L} \quad [13a]$$

This analysis is far from exact since it assumes a remote groundbed, uniform soil resistivity, and uniform defect density in the coating. At best, it demonstrates that attenuation is likely to follow an exponential decay and that it will be less severe for larger diameter pipes than for smaller diameter ones. The problem is more difficult to solve for more complex structures (e.g., congested pipeline networks) and especially so for marine installations where the development of the calcareous deposit introduces the possibility of temporal variations in attenuation.

The question of attenuation is not significant in the case of sacrificial anode protection systems where the individual source outputs are small.

#### 4.18.9 Summary

Cathodic protection is a long-established and proven technique for protecting metals from corrosion. While in principle it may be used to protect any metal in an aqueous environment, in practice it is used mainly to protect carbon steels in natural environments such as water, soil, and sand. Other metals often do not require protection because they do not corrode significantly under these circumstances. More aggressive environments render cathodic protection less attractive because of the substantial cost of providing the requisite current. Nevertheless, cathodic protection is applied to a vast area of metal on structures such as buried pipelines, ships, piers and jetties, oil production platforms, and liquid storage tanks. More recently, the protection of reinforcing bar in concrete has received attention. Cathodic protection is therefore of great technological significance.

There are two methods of applying cathodic protection, namely using an impressed current or a sacrificial anode. The former requires a source of DC power, but is then capable of delivering large voltages (<100 V) and currents (<100 A). A sacrificial anode operates independently of a source of DC power but only delivers a voltage of about 1 V and a current that will rarely exceed 5 A. The relative advantages of the two methods largely derive from these differences.

Cathodic protection benefits from its conjoint use with a coating on the structure; the current required for protection is reduced. However, in seawater,

the application of the technique encourages deposition of protective salts which to some extent achieves the same objective.

Since cathodic protection, if operated correctly, can prevent the corrosion of a metal entirely, it is unique among all the methods of corrosion control.

When two different metals are immersed in the same electrolyte, they will usually exhibit different electrode potentials. If they are connected by an electronic conductor, there will be a tendency for the potentials of the two metals to move toward one another; they are said to mutually polarize. The polarization will be accompanied by a flow of ionic current through the solution from the more negative metal (the anode) to the more positive metal (the cathode); therefore, electrons will be transferred through the conductor from the anode to the cathode. Thus, the cathode will benefit from the supply of electrons in that it will dissolve at a reduced rate; it is said to be 'cathodically protected.' Conversely, in supplying electrons to the cathode, the anode will be consumed more rapidly and will act as a 'sacrificial anode.'

From the above discussion, it is clear that, for an anode material to offer sacrificial protection, it must have an open-circuit potential that is more negative than that of the structure being protected (the cathode). The extent of protection experienced by the cathode will depend on the potential it attains. This is dependent on the electrochemical properties of the anode which in turn are governed by its composition and the environment to which it is exposed.

**4.19.1.1 Applications of Sacrificial Anodes**

The first recorded work on the application of sacrificial anodes was in the 1820s when Sir Humphrey Davy and his assistant Michael Faraday's work for the Royal Navy was reported in Philosophical Transactions of the Royal Society.<sup>1-3</sup> Their work centered

on the reduction of the corrosion of copper sheets attached to the wooden hulls of naval vessels. Davy identified that the corrosion was associated with differences in potential across the sheets of copper and, especially, where adherent corrosion products were present. By attaching pieces of zinc wire to a coil of copper wire, Davy demonstrated the process of sacrificial anode cathodic protection; he expanded this to larger scale trials and, finally, to full-scale trials on the HMS Sammarang and the Carnbrea Castle using anodes of cast iron.

When iron hulls became more common later in the nineteenth century, zinc sacrificial anodes were used to reduce corrosion; however, impurities, particularly iron, in the then commercially available zinc resulted in the formation of adherent nonconducting corrosion products of zinc on the anodes, which stifled the protection current flow and reduced the driving potential to unacceptable level.

Examples of the application of sacrificial anodes include ship, hulls and ballast tanks, offshore oil and gas drilling rigs, production platforms semisubmersibles and support facilities, underwater pipelines, underground pipelines, buried structures, harbor piling and jetties, floating dolphins, buoys, lock gates, and submerged concrete structures. There are many other uses including a large range of industrial equipment in which the surfaces are in contact with corrosive electrolytes, for example, heat exchangers, pump impellers, and vessel internals.

**4.19.2 Sacrificial Anode Basics****4.19.2.1 Anode Operating Potential, Protection Potential, and Driving Voltage**

The operating potential of an anode material is its potential when coupled with the structure under protection (i.e., the closed-circuit potential). Since commercial anode materials are formulated to suffer only limited polarization, under most conditions of exposure, the operating potential approximates to the open-circuit potential. Indeed, any substantial difference ( $>50$  mV) between these two potentials questions the suitability of the anode in the particular environment. For this reason, the open-circuit potential is usually used in design calculations wherein the operating potential is more precise but generally unknown at the time when the design is undertaken.

The protection potential refers to the potential at which experience shows that corrosion of a metal

**Table 1** Anode potentials of various alloys used in cathodic protection

<i>Alloy</i>	<i>Anode potential (V vs Ag/AgCl/ Seawater)</i>	<i>Max anode capacity (A h kg<sup>-1</sup>)</i>
Al-Zn-Hg	-1.0 to -1.05	2830
Al-Zn-Sn	-1.0 to -1.05	2600 (heat treated)
Al-Zn-In	-1.05 to -1.15	2700
Zn-Al-Cd	-1.05	780
Mg-Mn	-1.70	1230
Mg-Al-Zn	-1.50	1100-1230

will cease. Different materials have different potentials (Table 1). Occasionally, a less negative potential will be specified because some degree of corrosion is permissible. It should be noted that in a mixed metal system, the protection potential for the most base metal is adopted although the designer should take into account any deleterious effect that over protection may have on the nobler component and the need to supply excessive current if it is an efficient cathode. The cathodic protection of mixed metal systems can be a complex subject and is discussed in detail later in the chapter.

The driving voltage is the difference between the anode operating potential and the potential of the polarized structure to which it is connected. For design purposes, the driving voltage is taken as the difference between the anode open circuit potential (unless there are data on how the anode material will actually behave) and the required protection potential of the structure.

#### 4.19.2.2 Anode Capacity and Anode Efficiency

The anode capacity is the total coulombic charge (current  $\times$  time) produced by the unit mass of an anode as a result of electrochemical dissolution. It is normally expressed in ampere hours per kilogram (A h kg<sup>-1</sup>); however, the inverse of anode capacity, that is, the consumption rate (kg A<sup>-1</sup> year<sup>-1</sup>), is also sometimes used.

The theoretical anode capacity can be calculated according to Faraday's law. From this, it can be shown that 1 kg of aluminum should provide 2981 Ah of charge. In practice, the realizable capacity of the anode is less than the theoretical value. The significance of the actual (as opposed to the theoretical) anode capacity is that it is a measure of the amount of cathodic current an anode can give. Since anode capacity varies among anode materials, it is the

parameter against which the anode cost per unit anode weight should be evaluated.

The anode efficiency is the percentage of the theoretical anode capacity that is achieved in practice:

$$\text{Anode efficiency} = \frac{\text{Anode capacity}}{\text{Theoretical capacity}} \times 100\%$$

Anode efficiency is of little practical significance and can be misleading. For example, magnesium alloy anodes often appear to have an efficiency of around 50%, while for zinc alloys, the value exceeds 90%; it does not follow that zinc alloy anodes are superior to those based on magnesium. Efficiency will be encountered in many texts on sacrificial anode cathodic protection.

#### 4.19.2.3 Anode Requirements

The fundamental requirements of a sacrificial anode are to impart sufficient cathodic protection to a structure economically and predictably over a defined period, and to eliminate, or reduce to an acceptable level, corrosion that would otherwise take place.

In view of the above criteria, the following properties are prerequisites for the viability of a sacrificial anode<sup>4,5</sup>

1. The material must have a potential more negative than the potential at which corrosion ceases on the material being protected (i.e., the anode must exhibit a driving potential relative to the protected cathode). Thus, for steel, which is considered protected at potentials more negative than 0.8 V negative to the silver chloride seawater reference electrode, the driving voltage must be capable of overcoming the ohmic resistances of the anode cathode and the electrolyte in order to make the anode deliver the protection current. In practice this means a driving potential of at least 0.2 V more negative than the metal to be protected.
2. The driving potential of the anode must be stable with respect to time and must be predictably affected by the passage of current, that is, the anode material must have known and have acceptable polarization characteristics.
3. The anode material must have adequate capacity; that is, it must deliver an adequate and predictable number of ampere hours for every kilogram consumed.
4. The alloy must be capable of being formed by simple and economical processes into shapes in which it may be used, and it must have adequate

mechanical strength to remain in the desired form throughout its designed life.

5. The alloy must be commercially viable; that is, it must be capable of being produced in significant quantities (the world production of sacrificial anodes runs into many tens of thousands of tons per annum) and sold at a price that is acceptable to the users.

#### 4.19.3 Sacrificial Anode Materials

While cathodic protection can be used to protect most metals from aqueous corrosion, it is most commonly applied to carbon steel in natural environments (waters, soils, and sands). In a cathodic protection system, the sacrificial anode must be more electronegative than the structure. There is, therefore, a limited range of suitable materials available to protect carbon steel. The range is further restricted by the fact that the most electronegative metals (Li, Na, and K) corrode extremely rapidly in aqueous environments. Thus, only alloys based on magnesium, aluminum, and zinc are viable possibilities. These metals form the basis of the three generic types of sacrificial anodes.

In practice, with one minor exception (pure zinc), the commercially pure metals are unsuitable as sacrificial anode materials. This is because they fail to meet one or more of the prerequisites outlined above. For each basis metal, alloying elements are added to ensure more acceptable properties.

**Table 2** gives a list of the more important anode materials by broad categories, and some indication of their operating parameters. It is clear that there are major differences in performance between one generic type and another. Thus, the magnesium alloys have

very negative operating potentials and are therefore able to provide a large driving voltage for cathodic protection; zinc and aluminum alloys are more modest in this respect. Aluminum alloys, by contrast, provide a substantial current capacity which is more than twice that available from the zinc and magnesium alloys. It might appear that this implies that if the driving voltage is the most important feature in a given cathodic protection system (e.g., when there is a need for short-term high currents or a high resistivity to overcome), then magnesium alloys are to be preferred, but if a high capacity is required (e.g., steady delivery of current over a long life), aluminum alloys would be better. In practice, selection is significantly more complicated, and the topic is discussed in more detail in later sections.

Even within a generic type of alloy, there are significant performance differences. Thus, for example, Al–Zn–In alloys provide a higher driving voltage but a lower current capacity than Al–Zn–Hg alloys. Once a decision to use a generic type of alloy has been made, these apparently small differences in performance may become important in the final selection.

Alloying additions are made to improve the performance of an anode material.<sup>5</sup> Of equal importance is the control of the levels of impurity in the final anode, since impurities (notably iron and copper) can seriously adversely affect anode performance. Careful quality control of the raw materials used and the manufacturing process adopted is essential to sound anode production.

An intimate knowledge of the factors influencing the operation of sacrificial anodes and design parameters is essential if a full appreciation of how best to select an anode and achieve optimum performance is to be realized. The following considerations deal with those factors, which ultimately determine anode performance.

#### 4.19.4 Factors Affecting Anode Performance

##### 4.19.4.1 Alloy Composition

The constituent elements of anode materials, other than the basis metal, are present as a result of either being impurities in the raw materials or deliberate alloying additions. Impurity elements can be deleterious to anode performance; therefore, it is necessary to control the quality of the input materials in order to achieve the required anode performance. Since this will usually have an adverse impact on costs, it may

**Table 2** Typical basis material composition requirements for anode alloys

99.90% Magnesium		99.99% Zinc	
Cu	0.02 max	Pb	0.003 max
Mn	0.01 max	Cu	0.001 max
Sn	0.01 max	Cd	0.003 max

Cu	0.003 max	Cu	0.003 max
Ni	0.003 max	Ni	0.003 max
Cd	0.002 max	Cd	0.002 max

be desirable to tolerate a level of impurities and to overcome their action by making alloying additions. Alloying elements may also be added for other reasons, which are important to anode production and performance.

In general, sacrificial anode alloy formulations are proprietary and may be covered by patents. The patent documents are often very imprecise when they relate to compositions that will produce effective anodes and quite inaccurate in ascribing the function to a given alloying element. While the commercial literature is more specific when it relates to compositions, it rarely details the purpose of an alloying addition. In discussing alloy composition here, the treatment derives from the technical literature and is necessarily a broad-brush account. The reader is referred to the wealth of literature published over the past 50 years, for example, as reviewed by Googan.<sup>6</sup>

#### 4.19.4.2 Impurities

One important feature of an anode alloy is that it should dissolve with a capacity approaching the theoretical value. That is, all the electrons released by the metal dissolving should be transferred to the structure to support the cathodic reaction there, and should not be wasted in local cathodic reactions on its own surface.

In all the generic types of sacrificial anode alloys, the presence of iron is found to be deleterious. This is because an intermetallic compound formed between it and the basis metal proves to be a good cathode. Its presence will result in a substantial lowering of the capacity of an anode. Moreover, the presence of this cathodic material will often raise (make less negative) the anode operating potential and may, in the limit, promote actual passivation. Thus, the driving force available from the anode is reduced or completely destroyed. For example, when the solid solubility of iron in zinc (~14 ppm) is exceeded, the anode operating potential becomes more positive. This has been attributed to the formation of  $\text{Zn}(\text{OH})_2$  around intermetallic precipitates of  $\text{FeZn}_{13}$ .<sup>7</sup> The presence of iron has a similar adverse effect in aluminum<sup>8</sup> and magnesium<sup>5</sup> alloys.

There are two ways of avoiding the iron problem: to control the iron added with the basis metal or to sequester the iron in some way to render it ineffective. In practice, it is not possible to permit more than a limited iron content because sequestering is only economic and practicable within defined limits. The wider availability of electrolytically smelted zinc

with iron levels around 20 ppm means that iron is no longer an issue in the production of zinc anodes. The same is true for aluminum as world demand for higher purity ingot for the electronics industry means that aluminum with a notional purity of 99.85% is readily available with less than 0.08% iron and 99.90% with iron levels selectable at below 0.05%.

Other heavy metal impurities (especially copper and nickel) have similar adverse effects on all generic alloy types. In their case, sequestering has not proved successful, and control of input quality is used to keep their concentration acceptably low.<sup>5</sup> It is important that these impurities are specified at the time of selecting a supplier as what is a deleterious impurity to one application may be a beneficial ingredient to another; for example, levels of nickel in aluminum sourced in the Middle East were not considered relevant for most applications but resulted in significant reduction in capacity when used for anode production. Similarly, naturally occurring levels of gallium present in aluminum feedstock sourced in the United States for the development of Al–Zn–Si–In alloys contributed to the activation process, but when the alloy was licensed for production in the United Kingdom, locally sourced aluminum did not have the gallium impurity, and it had to be deliberately added to achieve the desired properties.

#### 4.19.4.3 Alloying Additions

We have seen that the adverse effect of impurities can, within limits, be controlled by alloying additions. Thus, silicon and aluminum are added to zinc and manganese to magnesium, to counter the effect of iron.

Additions are made for other purposes, all of which aim to improve the performance of the anode. These include lowering the anode operating potential to increase the driving voltage, avoiding passivation, increasing the anode capacity, improving the dissolution morphology, modifying the mechanical properties of the dissolution product to promote detachment, and improving the mechanical properties of the anode.

Table 3 lists some common zinc anode alloys. In three cases, aluminum is added to improve the uniformity of dissolution and thereby reduce the risk of mechanical detachment of undissolved anode material.<sup>5</sup> Cadmium was traditionally added to encourage the formation of a soft corrosion product that readily crumbles and falls away so that it cannot accumulate to hinder dissolution<sup>7</sup>; however, its use is now restricted due to environmental concerns. The Military Specification<sup>9</sup> material was developed to avoid the alloy

**Table 3** Standard zinc anode alloys

Capacity (A h kg <sup>–1</sup> )	780	780	780	780

passivating as a result of the presence of iron.<sup>5</sup> It later became apparent that this material suffered intergranular decohesion at elevated temperatures (>50 °C) with the result that the material failed by fragmentation.<sup>10</sup> The material specified by Det Norske Veritas<sup>11</sup> was developed to overcome the problem: the aluminum level was reduced under the mistaken impression that it produced the problem. It has since been shown that decohesion is due to a hydrogen embrittlement mechanism,<sup>12</sup> and that it can be overcome by the addition of small concentrations of titanium.<sup>13</sup> It is not clear whether the titanium acts as a getter for hydrogen or simply serves to refine the grains and increase the grain boundary area thereby diluting the embrittlement effect. It is claimed that recently developed alloys with magnesium additions are also resistant to intergranular attack at elevated temperatures.<sup>5,10</sup>

Although aluminum is a base metal, it spontaneously forms a highly protective oxide film in most aqueous environments; that is, it passivates. Consequently, it has a relatively noble corrosion potential and is then unable to act as an anode to steel. Low level mercury, indium, or tin additions have been shown to be effective in lowering (i.e., making more negative) the potential of aluminum; they act as activators (depassivators). Each element has been shown to be more effective with the simultaneous addition of zinc. Zinc additions of up to 5% lower the anode operating potential, but above this level, no benefit is gained. Below 0.9% zinc, there is little influence on the performance of aluminum anodes.<sup>5</sup> **Table 4** lists a number of the more common commercial alloy groups.

The best capacities in seawater are obtained from alloys containing zinc and mercury, but this is achieved at the expense of a somewhat more noble operating potential. Higher zinc additions at around 5% result in an alloy highly tolerant of burial in seabed muds.

Capacity (A h kg <sup>–1</sup> )	2700	Variable	2830

Mercury has become associated with environmental issues and is now seldom used in offshore applications. Zinc and indium additions give a less noble operating potential but are associated with a lower capacity. In practice this effect on the operating potential can be quite significant. The driving voltage between Al–Zn–Hg (open circuit/operating potential –1.05 V) and steel (protection potential –0.80 V) is 0.25 V. The use of Al–Zn–In provides a 20% increase in the driving voltage and thereby the possibility of a higher current output from equal sized anodes. Thus, both alloys have important advantages and disadvantages.

The Al–Zn–Sn alloys require careful solution heat treatment in their production to achieve optimum properties. Inevitably, this leads to more expense, longer production times, and a need for greater quality control. The advent of the alloys containing mercury or indium rendered these alloys very much

less attractive. Magnesium additions (0.1–2.0%) to Al–Zn–In alloys have been made, but it is not known whether this was a deliberate addition to improve a particular property or because the starting point for alloy development was an existing structural alloy. These materials can harden with age and hence suffer reduced ductility; since this can subsequently lead to longitudinal cracking of the anodes, they should not be cast in thin sections or stored at elevated temperatures (full sun in hot climates). Higher levels of magnesium (up to 8%), while improving strength and casting characteristics, incur the disadvantage of a reduced capacity.

Both titanium and boron can be added as grain refiners to ensure small grain size and hence high surface area grain boundaries.<sup>14</sup> This reduces the risk of preferential attack at grain boundaries and promotes more uniform dissolution. This effect also results in an alloy that is less susceptible to ‘hot shortness.’

Typical proprietary magnesium anode materials are given in **Table 5**. Magnesium anodes comprise two distinct types, the Mg–Mn and Mg–Al–Zn alloy systems. Addition of up to 1.5% manganese to high-purity magnesium yields a material with an operating potential of –1.7 V versus Ag/AgCl/seawater. The Mg–Mn alloys therefore exhibit very high driving potential and thus find application in particularly resistive environments. Mg–Al–Zn anodes have an operating potential (–1.5 V versus Ag/AgCl/seawater) 200 mV above that of the Mg–Mn alloys. This is very favorable in view of problems with overprotection. Thus, they are more popular in typical environments than the Mg–Mn alloys. The alloys also contain manganese, which is added to overcome the deleterious effects of iron.<sup>5</sup> Alloying additions of

aluminum, zinc, and manganese to magnesium serve to improve the anode capacity and reduce the operating potential, compared with that of pure magnesium. There is, however, no difference between the capacity of Mg–Mn and Mg–Al–Zn anodes. Mg–Al–Zn alloys are called ‘high purity’ when produced from virgin magnesium to distinguish them from a series of alloys developed after the Second World War when large amounts of magnesium alloy scrap were available.

#### 4.19.4.4 Metallurgical Factors

In producing anodes, the production method must not compromise the benefits of alloy formulation. A number of undesirable anomalies can occur during production, which may detract from the desired anode properties. Some of these anomalies are discussed below. A detailed account of finished anode requirements can be found elsewhere.<sup>11,15</sup>

Although most anodes are made by gravity casting, some are made by continuous or semicontinuous casting or extrusion. The method of casting affects the physical structure of the anode. That is, the associated cooling process will influence the segregation or distribution of alloying constituents. In some cases, it is undesirable to permit segregation since this may lead to preferential attack at grain boundaries. However, it is believed that segregation of activating elements during cooling benefits the performance of some alloys. This mechanism is a suggested explanation for the mercury- and indium-rich phases round on the surfaces of aluminum anodes.<sup>13</sup> The increased surface concentrations of these elements aid activation and are therefore beneficial.

Significant porosity within the anode is an indicator of the presence of dissolved gasses in the molten alloy and is an indicator of poor foundry practice and should be a cause for rejection and further investigation. The inclusion of extraneous matter, as a consequence of unclean foundry practices, may increase the tendency to fragmentation.

Cracking of anodes during casting is, in some cases, unavoidable due to the stresses imposed by cooling particularly those occurring between the cooling contracting anode and the mould heating and expanding. The problem is more common in Al–Zn–Hg anodes and less common when continuous or semicontinuous casting is used. Longitudinal cracks cannot be accepted, as these will lead eventually to mechanical loss of material. A greater tolerance to transverse cracks can be exercised although foundry practice and the use of grain refinement additions can

**Table 5** Proprietary magnesium anode alloys

<i>Alloy Component (wt%)</i>	<i>Mg–Mn (Galvomag®)</i>	<i>Mg–Al–Zn (high purity)</i>

minimize their occurrence. For example, one quality specification permits an anode completely supported by the insert to have transverse cracks of unlimited length and depth provided that there are no more than ten cracks per anode and their width does not exceed 5 mm.<sup>15</sup> This is somewhat arbitrary but emphasizes the point that cracks that threaten anode integrity are of greatest importance.

The anode material must stay firmly attached to the steel insert, which is necessary to conduct the current from the anode so that the structure remains effective, throughout its design life. Consequently, surface preparation of the insert prior to casting to ensure a sound bond with the anode material is essential. Voids at the insert–anode material interface are undesirable, as these will also affect the bond integrity. Dry blast cleaning to near white metal at the time of casting is the usual preparation for aluminum alloy anodes,<sup>15</sup> and coating by hot dip galvanizing or electrogalvanizing is used for inserts of zinc or magnesium anodes. Zinc coating of inserts for aluminum anodes must not be used as the coating enables the molten alloy to dissolve the insert.

#### 4.19.4.5 Environmental Factors

The conditions of environmental exposure play a key role in determining anode performance. Indeed, specific environments often preclude, or necessitate, the use of particular anode materials.

This section is not intended to deal with those environmental factors that influence cathodic current demand (e.g., oxygen availability or the presence of calcareous deposits) but those that directly affect the performance of the anodes.

Temperature is of particular importance to the performance of anodes, especially when anodes are buried. Anodes may often be used to protect pipelines containing hot products. Thus, temperature effects must be considered. Al–Zn–In anodes experience greatly reduced capacity in open seawater at temperatures above 70 °C<sup>16</sup> (down to 1200 A h kg<sup>-1</sup> at 100 °C) and in seabed muds in excess of 50 °C<sup>16,17</sup> (900 A h kg<sup>-1</sup> at 80 °C). At elevated temperatures, passivation of both aluminum alloys and pure zinc can occur.<sup>18</sup> Considerable improvement in performance (capacity, and to a lesser extent operating potential) has been claimed for a range of modified Al–Zn–In anode materials containing a deliberate alloying addition of silicon.

Zinc anodes have also experienced problems at elevated temperatures in saline mud, suffering intergranular decohesion at approximately 70 °C.<sup>19</sup> Later work by the same authors showed the threshold

for damage to be ~50 °C. The material is not recommended above 40 °C<sup>10</sup> although special zinc based materials for temperatures exceeding 50 °C have been developed.<sup>11</sup> Pure zinc, which does not suffer intergranular decohesion, will passivate under these conditions. It is claimed that newly developed Zn–Al–Mg anodes will perform satisfactorily at elevated temperatures.<sup>10</sup> Nevertheless, Al–Zn–In anodes have been specified for operation above 50 °C.<sup>10</sup> Furthermore, steps are now taken to ensure that the anode design prevents anode material being exposed to elevated temperatures under buried conditions.

It must be observed that most anode testing and development for use at elevated temperatures both in laboratories and in the field has been under isothermal conditions, and it is often erroneously assumed that the anode temperature is that of the product, whereas the anode is probably at a significantly lower temperature but is operating under high heat transfer conditions and that consideration should be given to placing a thermal barrier between the anode and the structure to minimize both temperature and heat transfer effects.

The presence of H<sub>2</sub>S (from bacterial activity in anaerobic saline mud, for example) can result in a significant decrease (16%) in capacity and loss of operating potential for Al–Zn–In anodes.<sup>17</sup>

Environmental resistivity and chloride content will affect anode performance. Aluminum alloy anodes require the presence of chloride ions to prevent passivation. Land-based applications generally provide insufficient chloride levels for this purpose. Consequently, aluminum alloy anodes predominantly find application in marine environments although some water produced from oil or gas wells is both saline and hot, and aluminum anodes find application in corrosion protection in vessels handling these fluids. The capacity and operating potential, of aluminum alloy anodes in particular, illustrated in [Figures 1 and 2](#), are dependent on the degree of salinity. With reducing salinity, the anode capacity will decrease and the operating potential rise. This becomes increasingly significant below 10–20% seawater strength and is important for design in estuarine conditions. Passivation of aluminum zinc indium alloy anodes may occur as a consequence of electrolyte stagnation, particularly, if the anode is immersed in silt or sand; zinc and Al–Zn(5%)–Hg perform reasonably under these conditions.

The capacity of an anode is dependent on the anode operating current density.<sup>16</sup> To some extent, it will be governed by its environment but, in part, is within the control of the design. Certainly, wholly unsuitable current densities can usually be avoided

**Figure 1** Electrochemical potential of aluminum and zinc anodes as a function of salinity and current density.

**Figure 2** Capacity of aluminum and zinc anodes as a function of chloride ion concentration and current density.

by correctly sizing the anodes. At lower operating current densities, some anodes exhibit reduced capacity; this is shown in [Figure 3](#). Long periods of low operating current density can lead to passivation. This may result in failure to activate when the current demand increases (as can occur with anodes on coated structures when the coating deteriorates).

#### 4.19.5 Selecting the Appropriate Anode Material

It is desirable to choose an anode material with the lowest cost per ampere hour of current supplied.

However, the choice is often governed by other constraints and frequently becomes a compromise.

##### 4.19.5.1 Zinc

Of all the anode materials, zinc is arguably the most reliable. It has, with few exceptions, reliable electrochemical performance; the exceptions lie within the area of high temperature operation. Zinc provides the lowest driving voltage of the generic alloy types. It is therefore unsuitable in highly resistive soils, except possibly as a ribbon, and in low salinity waters. However, an operating potential of  $-1.05$  V versus

**Figure 3** Capacity of an aluminum anode as a function of current density in seawater.

Ag/AgCl/seawater cannot lead to overprotection, which is an advantage where concerns for coating disbondment and hydrogen damage of high strength steel ( $>700$  MPa) exist.<sup>11</sup>

Zinc anodes have a poor capacity ( $780 \text{ A h kg}^{-1}$ ) compared with aluminum ( $>2500 \text{ A h kg}^{-1}$ ) although with its much higher density equivalent life anodes are frequently of similar dimensions. However, zinc is not susceptible to passivation in low chloride environments or as a consequence of periods of low operating current density. The reliable operational characteristics of zinc often outweigh the apparent economic attraction of aluminum, which can passivate under such conditions. At the time of writing, raw zinc costs about half the price of aluminum, which can significantly contribute to enhancing the appeal of zinc.

Zinc anodes do not find application at temperatures in excess of  $50^\circ\text{C}$ . Zn–Al–Cd alloys suffer intergranular decohesion, and high purity zinc will passivate. Zinc anodes are not predominant in onshore or offshore applications, but they find use under both conditions. The use of zinc anodes on fixed structures in the North Sea is now proscribed under EU regulation (Paris Convention).

#### 4.19.5.2 Aluminum

The great attraction of aluminum anodes is their very high capacity, over three times that of zinc. They are attractive from a cost point of view and also offer

substantial weight savings, which can be of great importance (e.g., offshore structures wherein the float-out weight is of paramount importance and the cost of increased weight of anodes can be many times the cost of the anodes and their installation).

Aluminum anodes comprise essentially three generic types: Al–Zn–In, Al–Zn–Hg, and Al–Zn–Sn. Since Al–Zn–Sn alloys have largely been superseded, they will not be discussed further. Indium and mercury are added to aluminum to act as activators, that is, to overcome the natural passivation of aluminum. Despite this, aluminum anodes are not suitable for low chloride environments, which would lead to passivation. These anodes are therefore not used for land-based applications (although examples of use in environments such as swamps do exist). Similarly, their use in low chloride aqueous environments such as estuaries must be viewed with caution.

Traditionally, the technical choice between Al–Zn–In and Al–Zn–Hg anodes is influenced by their respective operating potentials and capacities; however, more recently the environmental concerns have restricted the use of mercury-containing anodes. Where an additional driving voltage is required (such as in seabed mud), Al–Zn–In anodes may be preferred to ensure adequate structure polarization. Alternatively, a lower driving potential may be acceptable where the additional capacity (and hence weight saving) is the predominant factor; this favors Al–Zn–Hg anodes.

Aluminum anodes are less constant in their electrochemical characteristics than zinc. This presents no major problem provided the designer is aware of their properties. They suffer from reduced capacity and increased operating potential (and hence risk of passivation) with increasing temperatures above approximately 50 °C, decreasing salinity (Figure 2) and decreasing operating current density (Figure 3).

Aluminum alloys are susceptible to thermite sparking when dropped on to rusty surfaces. Consequently, their use may be subject to restrictions. For example, in ships' tanks where explosive gases or mixtures of gases can accumulate, the weight of the anode and the height at which it is suspended are strictly controlled. This is because thermite sparking is dependent on the kinetic energy of the anode released on impact, should it fall.

#### 4.19.5.3 Magnesium

Magnesium anodes are of two generic types, Mg–Mn and Mg–Al–Zn. Both alloy systems have a high driving voltage and therefore find application in high resistivity environments: soils and fresh, or brackish waters, for example. The Mg–Mn alloy is useful in particularly resistive environments (up to 6000  $\Omega$  cm) as a result of an available driving voltage 200 mV greater than Mg–Al–Zn anode. Because magnesium is nontoxic, its use is permissible in potable water systems wherein the conductivity is low.

The high driving voltage may, however, result in overprotection. Combined with relatively poor capacity (1230 A h kg<sup>-1</sup>) and high unit cost, these disadvantages mean that magnesium rarely finds application in subsea environments where alternatives are available. Despite this, Mg–Al–Zn anodes have been used in seabed mud and for rapid polarization of structures (in ribbon form).

The susceptibility of magnesium to thermite sparking when dropped onto rusty surfaces precludes its consideration for applications involving a spark hazard, for example, tankers carrying inflammable petroleum products.

#### 4.19.6 Anode Testing

Tests or sacrificial anode materials are generally conducted for three reasons: for screening (or ranking), performance information, and quality control. The application of sacrificial anodes for the protection of structures requires the development of suitable anode materials for the exposure environment.

1. Screening tests enable the rapid selection of materials that show potential as candidates for the given application. These tests may typically use a single parameter (e.g., operating potential at a defined constant current density) as a pass/fail criterion and are normally of a short duration (usually hours) with test specimen weights of the order of a few tens or hundreds of grams. The tests are not intended to simulate field conditions precisely and often include cutting samples from larger castings and surface preparation to give uniformity/across tests.
2. Performance testing is long term (months to years). Once a potentially attractive formulation has been identified, it is usual to produce detailed data on its performance and behavior as an anode material under the anticipated exposure conditions. For this reason, the test should mirror as closely as possible the expected operating conditions, or where practicable be conducted in the field. Large specimens (tens or hundreds of kilograms) in the as cast condition would be used for these tests.
3. Quality control tests are intended to detect produced materials that deviate from manufacturing specifications, and thus may result in questionable performance. This area of anode testing has probably been the subject of more debate and controversy than any other. The anode alloy is usually subjected to chemical analysis usually by spark emission spectroscopy, which is the primary quality control check. The preparation of samples for this testing, especially if small samples from the melt or samples that are cut from a full anode are to be used, must be validated to ensure that analysis is not corrupted by surface preparation. The risk is reduced if the analytical technique uses dissolution of the sample when surface preparation is irrelevant.
4. Exposure testing has generated a whole industry of quite dubious value to the final product. It was first developed to act as a quality check on the efficacy of solution heat treatment of Al–Zn–Sn alloy anodes when a simple capacity test based on measurement of hydrogen evolved under impressed current was used as a go or no-go acceptance test. Samples, heat treated alongside full sized anodes, were tested overnight. Unfortunately, the results were expressed in the same units as anode capacity, and electrochemical testing has now been mandated to do a job that was never intended, that is, to confirm the actual long-term performance of full sized anodes in service. The use of short-duration (hours or days) tests on small samples, which have had some form of surface treatment not typical of

full-sized anodes, in which the test conditions attempt to reflect the environment of operation, for example, using artificial seawater for a marine application, cannot and never will reflect full-scale operation. In more than 30 years of experience, this author has not heard of a single instance in which a sensible sized anode (>10 kg) made from a correctly formulated alloy has failed to deliver electrochemical performance as expected. Conversely, the examples of small-scale tests on samples giving erratic results are legion, and the subsequent contractual and so called scientific wrangles have contributed nothing to corrosion control.

#### 4.19.7 Cathodic Protection System Design

##### 4.19.7.1 Design Parameters

Before a satisfactory cathodic protection system using sacrificial anodes can be designed, the following information has to be available or decided upon:

1. the area of the steelwork to be protected;
2. the type of coating, if any, that is to be used;
3. the cathodic current density;
4. cathodic protection system life.

While the data given here is general guidance for many situations, detailed guidance will be given in classification society or client rules, and these will take precedence and may change based on the experience gained in actual operation.

#### 4.19.8 Area of Steel Requiring Protection and Coating Considerations

The area of bare steel to be protected is usually calculated from drawings and knowledge of the actual structure and must account for all electrically continuous steelwork exposed to the electrolyte. Steelwork not specified in drawings and subsequently overlooked is a common cause of underdesign. In one classic example, the current drain to the conductors of an offshore production platform was ignored with near disastrous consequences and a requirement for a gigantic retrofit program. In practice, the area is usually taken assuming the steel surfaces to be flat without corrugations, indentations, or surface roughness. An allowance for uncertainties in real area is normally involved.

Many structures, especially pipelines, are coated. Thus, the presented area far exceeds the area of steel

to be protected, which is restricted to uncoated areas and holidays in the coating. It is therefore good practice to assume an arbitrary level of coating breakdown for coated areas to obtain the area of metal requiring cathodic protection. During installation of larger diameter subsea pipelines (>8 in. dia), pipe sections are prepared in 40 ft lengths onshore where coating integrity can be rigorously controlled; however, field joints are often made under severe constraints as the pipe is prepared to go over the stinger. It is therefore often assumed that these field joints will fail, and 2.5% coating loss is used as the basis for design

$$\text{Area to be protected} = \frac{\text{Presented area} \times \% \text{ breakdown}}{100}$$

Breakdown will vary through the life of a structure with the result that the area requiring protection will change. Various estimates of coating breakdown have been made, and Table 6 provides an example based on a single coat epoxy coating system on blast cleaned steel exposed to seawater, for example, a subsea completion structure. Table 6 reasonably assumes a rate of breakdown that varies with time; this will be much greater for fully exposed surfaces compared, for example, to pipeline coatings which may be overlaid with several centimeters of reinforced concrete which are then trenched into the seabed, as are shown alongside. A ship's hull may be expected to lose 10–20% or even more of its coating system in a relatively short period dependant on operating location. The significance of the area of steelwork is that the greater the area, the greater the weight and/or the area of anode material required for protection.

#### 4.19.9 Cathodic Current Densities for Protecting Steel

Examples of current density requirements for the protection of steel (to achieve a steel potential of  $-0.8$  V

**Table 6** Guidance on coating breakdown for offshore structures

<i>Steel structures fully exposed simple epoxy coating</i>			
Lifetime (years)	Coating breakdown %

Indonesia	110	60	80
Saline mud	25	20	15

versus Ag/AgCl/seawater) are given in [Tables 7](#). It should be realized that the current demand of a structure will be influenced by, *inter alia*, temperature, degree of aeration, flow rate, protective scales, burial status, presence of bacteria, and salinity.

It is important that the correct current density requirement is assigned for design purposes. If too high a value is used the structure may be overprotected and anode capacity wasted. On the other hand, if too small a value is used it will mean that the protection system will not achieve its design life.

#### 4.19.10 System Life

Cathodic protection systems may be designed with a life as short as 1 year or more than 40 years. The greater the time of protection, the greater the mass or anode material that is required.

Intermittent exposure and local conditions need to be considered also. The ballast or storage tanks of ships will experience periods of complete submergence and partial coverage, and may at times be empty. Similarly, the wetted areas of offshore structures may be governed by tidal and seasonal variations. Local requirements must therefore be considered in order to achieve the optimum amount of anodic material to achieve the life of the system.

##### 4.19.10.1 Calculating the Weight and Number of Individual Anodes

Firstly, the total weight of anode required to protect the structure for its projected life is calculated. This is given by:

$$W = \frac{i_{av} A l \times 8760}{C}$$

where  $W$  is the total mass of anode material (kg);  $A$ , the structure area to be protected (m<sup>2</sup>);  $i_{av}$ , the mean structure current density demand (A m<sup>-2</sup>);  $l$ , the design life in years (1 year = 8760 h); and  $C$  is the anode capacity (A h kg<sup>-1</sup>).

Obviously, the total weight of the anode material must be equal to or be greater than the total weight,  $W$ , calculated above. Similarly, each anode must be of sufficient size to supply current for the design life of the cathodic protection system. The anodes must also deliver sufficient current to meet the requirements of the structure at the beginning and end of the system's life. That is, if current demand increases (as a result of coating breakdown, for example), the output from the anodes should meet the current demands of the structure.

##### 4.19.10.2 Anode Size and Shape

In practice, while there is often an extensive range of suitable anode sizes to select from, economics may dictate a bespoke anode for a project depending on its precise requirements. Computer programs are used to optimize (minimize) the number of anodes required to satisfy the often conflicting protection requirements. The cost of the anode insert in a platform anode may be close to that of the anodic material, and the cost of lifting, welding, etc. is substantially more than that of the anode. Furthermore, after a set of moulds has been used to produce several thousand anodes, they will probably only be fit for recycling.

The current output from an anode will depend on its resistance, which will be a direct function of shape and size. Generally, larger anodes will have a higher current output. Anodes of the same weight but differing shape can have different outputs because the surface area to weight ratio will not be equal for all possible dimensions. Thus, for a given weight of anode, the shape will offer a degree of flexibility when considering current output.

##### 4.19.10.3 Anode Output

Anode output is the current available from the anode under the design conditions. It will depend on the shape of the anode, the resistivity of the environment, the protection potential of the structure, and the anode operating potential. It is defined as:

$$I = \frac{[E_2 - E_1]}{R}$$

$I$  is the anode output (A);  $E_1$ , the operating potential of the anode (V);  $E_2$ , the protection potential (V); and  $R$  is the anode resistance ( $\Omega$ ).

The protection potential of steel in aerobic environments is taken as  $-0.80\text{ V}$  (versus  $\text{Ag}/\text{AgCl}/\text{seawater}$ ).

#### 4.19.10.4 Anode Resistance

**Table 8** lists some of those formulae suitable for the calculation of anode resistance,  $R$ , under submerged conditions. Some are based on earth resistance effects and modifications of the formulae used in the design of electrical earthing systems, while others are purely empirical. Similar formulae exist for anodes in buried conditions. These have been extensively researched and reviewed.<sup>20–24</sup>

To calculate the anode resistance, a knowledge of the environmental resistivity is required. For submerged anodes, the water resistivity can be obtained from graphical representations such as in **Figure 4**, provided that the temperature and water density are

known. However, field data are preferable, and, in the case of soils that can have widely varying resistivities, they are essential.

#### 4.19.10.5 Anode Life

Having calculated the resistance, and hence the current output, the anode life,  $L$ , is checked by the calculation:

$$L = \frac{MU}{IE}$$

where  $L$  is the effective life of anode (years);  $M$ , the mass of single anode (kg);  $U$ , the utilization factor, for example, 0.75–0.80 for bracelet anodes and 0.95 for platform anodes;  $E$ , the consumption rate of the anode ( $\text{kg A}^{-1} \text{ year}^{-1}$ ) (inverse of capacity in suitable units); and  $I$  is the anode output (A).

**Table 8** Table of anode resistance formulae DnV RP B401

Anode type	Resistance formula
Long slender stand-off <sup>a,b</sup> $L \geq r$	$R_a = \frac{\rho}{2\pi L} \left( \ln \frac{4L}{r} - 1 \right)$
Short slender stand-off <sup>a,b</sup> $L < 4r$	$R_a = \frac{\rho}{2\pi L} \left[ \ln \left\{ \frac{2L}{r} \left( 1 + \sqrt{1 + \left( \frac{L}{2L} \right)^2} \right) \right\} + \frac{r}{2L} - \sqrt{1 + \left( \frac{r}{2L} \right)^2} \right]$
Long flush-mounted <sup>b</sup> $L \geq 4$ width and $L > 4$ thickness	$R_a = \frac{\rho}{2S}$
Short flush-mounted, bracelet and other types	$R_a = \frac{0.315\rho}{\sqrt{A}}$

<sup>a</sup>The equation is valid for anodes with minimum distance 0.30 m from protection object. For anode-to-object distance minimum 0.15 m the same equation may be applied with a correction factor 1.3.

<sup>b</sup>For noncylindrical anodes:  $r = c/2\pi$  where  $c(\text{m})$  is the anode cross-sectional periphery.

Source: DnV RP B401 (2005) – Recommended practise for cathodic protection design.

**Figure 4** Resistivity as a function of specific gravity for seawater/fresh water mixtures.

$U$  is purely a function of anode geometry and is the fraction of anode material consumed when the remaining anode material cannot deliver the current required or the anode can no longer be supported by its insert.

Excessive anode life is of no benefit. If the calculated life is unsuitable a different anode size and/or shape should be considered. However, this may not always be possible, especially for short-life, coated structures, when dimensional constraints on the anodes may be imposed.

#### 4.19.10.6 Number of Anodes

The total number of anodes,  $N$ , is calculated from:

$$N = \frac{Ai_{ay}}{I}$$

This calculation should yield a practicable number of anodes; that is, 10 or 10 000 anodes are both clearly unacceptable for the distribution of protection. On an offshore oil production platform,  $N \times M$  must be equal to, or greater than, the total weight or anode material,  $W$ , required.

It is also useful at this point to consider the limitations imposed by the production processes and the actual application of the anode. For a platform anode, hypothetically, the anode could be almost as long as the water depth, but first such an anode would have such a large mass and consequently inertia that it would be unlikely to survive the installation or piling processes and would be torn off. Using a stronger insert and attachment configuration would result in such a large diameter core relative to the body cross section that the anode material could reasonably be expected to split longitudinally during the solidification and subsequent cooling. Some of these could be overcome by semicontinuous casting rather than horizontal gravity casting. However, this process, originally developed for production of extrusion ingots still, has the limitation of the depth of the pit into which the casting is discharged and the lifting equipment servicing it. In order to minimize the likelihood of some or all of these, for all practical purposes, the maximum core diameter of a platform anode is 150 mm, and for this to be cast into an anode, the cross section would have to give at least 100-mm depth of cover of the anodic material over the insert. While some foundries design a small cross-section taper over the length of the anodes, others use very heavy preheated wall moulds and inserts (or both) to minimize anode mould interaction. Unless the mould/insert is heated to the casting temperature of

the anode alloy, the mould and insert will continue to expand as the anode solidifies and contracts, and transverse cracking of the anode becomes more probable. Grain refinement increases the high strength of the alloy, but there are limits to how much can be done. Typically, a maximum anode length of 3 m and a maximum weight of 500 kg have been imposed as practical limitations. Bracelet anodes for submarine pipelines are often sized to match a weight coating thickness where there is no weight coating. The thinner the anode, the lesser the impact as it goes over the stinger during laying. Many of the same limitations that applied to platform anodes also apply to bracelets although thin wall moulds and water cooling have assisted reducing anode thickness where necessary. Bracelet diameters are governed by pipe diameters and thickness by laying or coating considerations, but they are unlikely to be viable at more than 1.5 m long and 400 kg in weight. Needless to say, some readers will be able to quote examples of anodes larger than those implied here, but they will be few and far between and almost certainly associated with some special circumstance; for example, a very large platform anode mounted on a sea bed sled or a bracelet designed to be mounted on a large pipe to be retrofitted to a platform to compensate for a shortfall in the original design.

It can be difficult to achieve both the exact current output and precise weight of anode material simultaneously although, as mentioned previously, the use of iterative calculation by a computer program can optimize this. Where a compromise is necessary, both must at least match design requirements.

A check to ensure that the anodes will deliver sufficient current to protect the structure at the end of the design life should be conducted. This entails calculating the expected anode output at the end of its life and checking that it meets the demands of the structure. Generally, the output is calculated using a modified resistance based on an anode that is 90% consumed.

#### 4.19.10.7 Anode (End Current) Distribution

It is evident that a greater number of anodes distributed over the structure will improve current distribution. However, aside from the unacceptable cost incurred by attaching excessive numbers of anodes, an anode must continue to function throughout the life of the structure and must, therefore, be of sufficient size to meet the design life. A very large number of heavy anodes is clearly impracticable and uneconomic.

It is essential to ensure adequate current distribution such that all of the exposed structure remains

protected; particularly important, for example, for the nodes of an offshore steel structure. Similarly, over-protection should be avoided. Thus, sacrificial anodes need to be distributed to ensure that the protection potential over the whole structure is achieved.

The proximity of the anodes to structures is also important. For example, if the sacrificial anodes are placed on or very close to the steel pipework in soil, then the output from the face of the anodes next to the steelwork can be severely limited. Alternatively, in high conductivity environments, corrosion products may build up and wedge between the anode and the structure. The resulting stresses can lead to a mechanical failure of the anode. On the other hand, when anodes are located at an appreciable distance from the steelwork, part of the potential difference will be consumed in overcoming the environmental resistance between the anode and cathode.

Complex computer models are now available to assist in defining the optimum anode distribution.<sup>25</sup>

#### 4.19.10.8 The Anode Insert

The anode insert must be strong enough to support the weight of the anode and must be capable of being welded, or mechanically fixed to the cathode.

It should be appreciated that the attachment may be required to withstand the launching and pile driving of a steel jacket for offshore applications.

Consideration must be given to the ease and speed of anode fixing, as this is a significant part of the total installation cost. The methods of fixing anodes to flat, vertical or horizontal surfaces are relatively well known and simple. The methods of fixing anodes to curved surfaces of pipelines and immersed structures are more complex, and generally require more steel insert. **Figure 5** shows typical anodes in common use offshore on jackets and pipelines.

While catalogues of proprietary platform anodes often show a wide variety of attachment arrangements involving tube, angle, channel, and other sections, it must be remembered that most anodes are attached to structural tubular members of a stressed structure subject to significant cyclic forces during installation, piling, and service (wave impacts). The welds between anode insert and structure have to be designed to avoid fatigue failure; not only will this involve, in most cases, the doubler plates of a metal compatible with both anode and structure but also full penetration welds that are subject to most stringent inspection (probably radiography) and the avoidance of stress raisers,

**Figure 5** Typical anodes in common use offshore on jackets and pipelines.

meaning that only all tubular inserts are likely to be acceptable. Bracelet anodes are usually clamped around the pipe with little or no welding between inserts, and pipe steel electrical connection is achieved by a low temperature connection process such as copper thermite welding or pin brazing with a very small contact area, but even then usually to an expendable doubler plate.

#### 4.19.10.9 Utilization Factor

This component of anode design calculation is worthy of serious consideration as too often a figure of 0.9 or 90% is used for platform anodes and 0.75–0.85 or 75–85% for bracelets without understanding where it originates from. Essentially, the utilization factor reflects how much of the net weight of an anodes delivers useful cathodic protection before it becomes structurally unstable and (literally) falls to pieces. Examination of long thin anodes, which are cast on tubular inserts, towards the end of their life reveals that the attack on the original rectangular cross section approaches a final circular appearance.

Moreover, the attack is preferential towards the ends of the anode such the overall appearance approximates to a traditional 'cigar' shape while it remains supported by the insert. Anodes with a stand-off at least 300 mm from the structure being protected in open seawater are unlikely to be seriously affected by proximity and corrode nonuniformly. Anodes installed close to the structure should have an inert nonconducting coating (coal tar epoxy) on the face closest to the structure to minimize preferential attack on the close face and the possibility of anode corrosion products building up behind the anode and forcing it off. This is of particular importance for bracelet or hull anodes and much less so for platform anodes.

For pipeline or hull anodes, the distance through the anode that the insert is placed directly influences the utilization factor since; if, for example, the insert is in the centre of the anode mass, the utilization factor will be 0.5 or 50%; if it were on the front face, the  $U/F$  would theoretically be zero and on the back face, 1.0, although none of these would be practical. Thus, if the insert is 75% of the depth of the anode from the front face, then the utilization factor is likely to approximate to 75%. Ingenious designs of insert involving a backing plate with a mesh embedded in the back face of the anode material in order to approach a  $U/F$  of 1.0 have been patented but are not in common use.

#### 4.19.10.10 Backfills for Anodes

When zinc or magnesium anodes are used for cathodic protection onshore,<sup>25–28</sup> they are usually surrounded by a backfill, which decreases the electrical resistance of the anode. Small anodes are usually surrounded with backfill in bags and large anodes are usually surrounded with a loose backfill during installation. The backfill prevents the anode coming into contact with the soil and suffering local corrosion, thus reducing the capacity. By surrounding the anodes with a backfill, the combination of the anode with soil salts is reduced, and this helps prevent the formation of passive films on the anode surface.

The effect of the backfill is to lower the circuit resistance and thus reduce potential loss due to the environment. The additive resistances of the anode/backfill and backfill/soil are lower than the single anode/soil resistance. Backfills attract soil moisture and reduce the resistivity in the area immediately round the anode. Dry backfill expands on wetting,

and the package expands to fill the hole in the soil and eliminate voids.

For use in high resistivity soils, the most common mixture is 75% gypsum, 20% bentonite, and 5% sodium sulfate. This has a resistivity of approximately 50 ohm cm when saturated with moisture. It is important to realize that carbonaceous backfills are relevant to impressed current anode systems and must not be used with sacrificial anodes. A carbonaceous backfill is an electronic conductor and noble to both sacrificial anodes and steel. A galvanic cell would therefore be created causing enhanced dissolution of the anode, and eventually corrosion of the structure.

### 4.19.11 Other Considerations

#### 4.19.11.1 Calcareous Scale

A consequence of cathodic protection in seawater is the formation of a protective calcareous scale.<sup>29</sup> The increased local pH at the steel surface caused by hydroxyl production (a product of the cathodic reaction) favors the deposition of a mixed scale of  $\text{CaCO}_3$  and  $\text{Mg(OH)}_2$ . This scale is beneficial since it is protective and nonconducting, thus reducing the cathodic current density. Ensuring a high current density in the early period of operation will encourage calcareous scale deposition and thus reduce the current requirements in the long term.

The build-up of calcareous deposits is a complex topic. Very high current densities will not necessarily result in the most protective scale. In the extreme, hydrogen evolution may rupture the scale resulting in reduced protection. An optimum current density will exist, and this should be recognized.

#### 4.19.11.2 Combined Alloy Anodes for Rapid Structure Polarization

Combined (or binary) alloy sacrificial anodes have been developed.<sup>30</sup> An aluminum anode, for example, might have attached to it a short-life supplementary magnesium anode, or anodes, for quick polarization of the structure. The overall reduction in structure current requirements is claimed to result in an anode weight saving of 35–50%. This derives from the increased current output from the anode early in its operating life, giving rise to a relatively protective calcareous scale, which then reduces the current demand for protection later in life.

**4.19.11.3 Flame Sprayed Aluminum**

The use of flame sprayed aluminum (FSA) with a silicon sealer paint has been applied to protect high-strength steel tension legs of a North Sea production facility.<sup>32</sup> The FSA system primarily acts as a very effective barrier coating. In addition, the coating has significant anodic capability and aluminum corrosion products serve to plug coating defects. The sealer, although reducing the anodic current output, serves to increase the service life of the FSA coating. This coating system is subject to strict control of application procedures.

**4.19.11.4 Protection of High-Alloy Steels**

High-alloy pipeline steels (e.g., austenitic–ferritic or duplex) have been used where the product stream demands materials with better corrosion resistance than carbon steel. In practice, the external corrosion resistance of these materials cannot be guaranteed, so cathodic protection is employed to protect areas which may be subject to corrosion.

Concern about hydrogen damage has led to much debate regarding limits for protection potentials of high-alloy steels. However, it is thought that under normal seawater service and cathodic protection conditions, these materials will not be adversely affected provided that the microstructure has at least 40% of austenite present. This latter point is of particular importance to welds and their heat affected zone where careful control of heat input is necessary to maintain a favorable microstructure.

The latter part of this chapter has dealt with the design considerations for a sacrificial anode cathodic protection system. It has outlined the important parameters and how each contributes to the overall design. This is only an introduction and guide to the basic principles of cathodic protection design using sacrificial anodes and should be viewed as such. In practice, the design of these systems can be complex and can require experienced personnel who will have to not only satisfy the needs of the protection system but also the client and the classification body, and not all of these are mutually compatible.

### Glossary

**Backfill** A material having preferred properties, such as conductivity, noncorrosiveness, etc., and that is emplaced around an anode in order to enhance its performance.

**Groundbed** The location of one or more buried anodes in, for example, soil, mud, etc.

### Abbreviations

**AC** alternating current

**ASTM** American Society for Testing and Materials

**BS** British Standard

**DC** direct current

**DSA** Dimensionally stable anodes

**HSI** High-silicon iron

**MMO** Mixed metal oxides

## 4.20.1 Introduction

The ideal anode for impressed-current cathodic protection (CP) would be capable of passing the required current into the environment, at a low operating overpotential, with insignificant loss of material with time. The first application of impressed-current systems used steel anodes which were Faradaically consumed during operation. Later anodes replaced such metal dissolution with the evolution of oxygen or chlorine, depending on the composition of the environment. The lower anode dissolution rate associated with such evolution then depends on the properties of the surface film produced (usually an oxide) and its resistance to the evolved oxidizing gases. Thus, the oxygen evolved on graphite forms some carbon dioxide consuming some of the carbon in the process. Lead and silicon iron anodes rely on the formation of an insoluble but conductive oxide film allowing current to pass while significantly reducing, but not eliminating, metal loss.

This reduction in anode consumption because of oxide formation is most efficient on platinum, where the loss rate is of the order of  $1.0\text{--}10\ \mu\text{g A}^{-1}\text{h}^{-1}$ . Further reductions in dissolution rate have come with the development of the most recent anode materials, which effectively dispense with the underlying dissolving metal by using a coating consisting solely of oxides (e.g., mixed metal oxides, MMO), supported on an anodically inert substrate (titanium). Even at high currents, these anodes are consumed at a rate which can be as much as an order of magnitude less than that seen on platinum. These latter materials probably represent the ultimate to be achieved in anode performance.

The various types of materials which have been, or are, used as anodes in impressed-current systems may be classified as follows:

- Ferrous materials: steel, cast iron, iron, stainless steel, high-silicon iron, high-silicon molybdenum iron, high-silicon chromium iron, magnetite, ferrite.
- Lead materials: lead–antimony–silver, lead with platinum alloy microelectrodes, lead/magnetite, lead dioxide/titanium, lead dioxide/graphite.
- Carbonaceous materials: graphite, carbon, coke breeze, conductive polymer, conductive paint.
- Precious metals and oxides: platinum, platinized titanium, platinized niobium and tantalum, mixed metal oxide-coated titanium, titanium oxide-based ceramics.

Each group is discussed in detail in the following sections, while the final sections briefly describe those that are presently employed in common CP scenarios.

## 4.20.2 Ferrous Materials

### 4.20.2.1 Steel

One of the earliest materials to be used in impressed current CP was carbon steel. Although it has severe limitations, it has sometimes been found to be cost effective in situations where steel scrap is available in suitable quantities and geometry, and it is only in such situations where its use would now be considered. Steel anodes have found particular use in seawater, with a surprising variety of forms being reported to have been utilized, for example, pipes, piling, machinery, rails, and even obsolete ships which have not been economic to salvage. When used as an anode, the consumption rate of steel is close to the theoretical, Faradaic value of  $9.1\ \text{kg A}^{-1}\text{year}^{-1}$ . Consumption rates in excess of the theoretical value have been reported for steel in some waters.<sup>1</sup>

When buried, ferrous anodes tend to exhibit high resistance polarization because of the formation of a voluminous corrosion product. This can be alleviated by closely surrounding the anode with carbonaceous backfill; this of course increases the cost if the backfill is also not a locally available by-product. It is necessary to ensure compactness and homogeneity of backfill at all areas around the anode, as otherwise rapid loss of metal at poorly compacted areas can occur.

In recent years, deep-well groundbeds for the protection of clusters of oil or gas wells have been provided by using the steel casings of otherwise abandoned wells in the same area. In order to provide conductance to the active length of the casing, the wells have been filled with carbonaceous backfill, such as coke breeze. Commercial examples of such installations are known to be working well after the period of 28 years.<sup>2</sup> It is necessary to take considerable care to ensure the integrity of anode cable connections and to use multiple connections to ensure redundancy in the event of cable failure. Connections must be encapsulated to protect them from the environment.

### 4.20.2.2 Cast Iron

Cast iron may be used under similar circumstances to steel, but has inferior mechanical properties. It has

been used, although not in recent times, for internal CP, of cooling water systems, where it has been demonstrated that the presence of ferrous ions in the cooling water is of benefit in reducing sulfide-induced attack on Cu alloy tube plate and tubes.<sup>3</sup> Ferrous sulfate dosing is now used as a more reliable means of achieving the same end.

#### 4.20.2.3 Stainless Steel

Stainless steel has been tried as an inert anode, mainly under laboratory conditions and with only partial success. Even at low current densities, the majority of alloys pit rapidly in fresh water, although others show the ability to remain passive at a low current density.<sup>4,5</sup> However, at practical current densities, the presence of chloride ions, deposits on the anode, or crevice corrosion at the anode support leads to rapid failure,<sup>6</sup> but it may be possible that stainless steel could give useful service under certain conditions and with particular alloys.<sup>7</sup>

#### 4.20.2.4 High-Silicon Irons (HSI)

##### 4.20.2.4.1 Iron-silicon alloys

High-silicon iron (HSI) anodes are cast-iron alloys that contain 14–18% Si and were first developed in 1912,<sup>8</sup> although it was not until 1954 that they were first evaluated for use as impressed-current anode materials in CP.<sup>1</sup> Their major disadvantages are those of a hard brittle material unable to withstand thermal or mechanical shock. HSI has a long and successful history as a corrosion-resistant material in the chemical industry for such items as acid storage vessels and has been used in this application for more than 60 years. A typical analysis for HSI anodes is 14.5% Si, 0.75% Mn, 0.95% C, and remainder Fe. The anodes conform to either BS 1591:1975 or ASTM A518–80 Grade 2. The latter lists the permissible Si content range as between 14.20 and 14.75. As the material is not readily machined, it is cast into standard sizes to suit the general requirements of the CP industry. Anodes can be cast as solid rods, or centrifugally cast cylinders.

Used as an anode, HSI readily forms a protective film, which is reformed if removed mechanically. The film is gray-white in appearance and has a tendency to flake under the compressive stress produced at thickened areas. The film is 50% porous and contains 72–78% SiO<sub>2</sub>.<sup>8</sup> It is a fairly good electron conductor,

even though SiO<sub>2</sub> in its natural state is a dielectric. The mechanism whereby the SiO<sub>2</sub> becomes a conducting oxide has been reviewed in some detail by Shreir and Hayfield,<sup>9</sup> and is probably associated with doping of the SiO<sub>2</sub> with Fe ions.

HSI anodes are subject to severe pitting in the presence of halide ions, and this precludes their use in seawater or other environments in which these ions may be present. They are suitable for freshwater applications (below 200 ppm Cl<sup>−</sup>), although not suitable for temperatures above 38°C. The addition of Mo or Cr to the alloy can improve performance under these conditions, with an upper limit temperature of 56°C,<sup>10</sup> which may be affected by the composition of the water and the operating conditions.

The consumption rate of HSI depends upon the current density and the environment in which the anode is used. HSI is superior to graphite in waters with resistivity greater than 10 Ω m, but in waters of 0.5 Ω m and below, it is susceptible to pitting. Experience in fresh water in the pH range 3 to 10 indicates a nominal consumption rate of approximately ~0.1 kg A<sup>−1</sup> year<sup>−1</sup> at 20°C. The precise value is dependent upon the solution composition and the temperature.<sup>11</sup> A number of reports on the performance of HSI anodes in different environments have been produced.<sup>11–14</sup>

The consumption rate of HSI anodes buried directly in soils will vary depending upon the soil composition and will be excessive in chloride-containing soils. In quicksand, consumption rates of ~0.35 kg A<sup>−1</sup> year<sup>−1</sup> have been reported,<sup>11</sup> while in other soils, consumption rates in the region of 1 kg A<sup>−1</sup> year<sup>−1</sup> are possible. A consumption rate in the region of 0.1–0.25 kg A<sup>−1</sup> year<sup>−1</sup> would be expected in a correctly installed carbonaceous backfill, when operating in a soil of insignificant chloride content and a surface current density of no more than 20 A m<sup>−2</sup>. Higher consumption rates would result from high local current densities, often caused by inadequate backfill, partial submersion, or silting. A coke-breeze backfill can be installed around the anodes when buried in higher resistivity soil, so as to reduce the overall resistance to the earth and enabling the use of higher current groundbeds. There is a tendency for the surface resistance of a buried anode to increase, but not to an extent that it affects performance. The large resistance changes sometimes reported for carbonaceous beds are usually due to gaseous polarization (gas blocking) caused by poor venting or by inadequate compaction of backfill.

With any impressed current anode, an effective connection is vital. Loss of insulation at the connection point or penetration of water into the anode cable seal will bring about rapid failure. Hydrostatic pressure should be borne in mind when considering the seal required for any depth of water. End connections for solid rod anodes use compression, cast lead, or taper pin connections, sealed by a combination of epoxy filling and heat shrinkable sleeves. Cylindrical anodes have center connections with taper wedges or cast lead. The useful life of HSI anodes is usually considered at an end after a 33% reduction in diameter, but this depends upon the original diameter, the amount of pitting sustained, and the mechanical stresses to be withstood. Therefore, doubling the cross-sectional area may more than double the effective life of the anode.

#### 4.20.2.4.2 *Silicon-molybdenum iron*

The addition of 1–3% Mo to HSI modifies the anodic oxide film resulting in improved performance in solutions containing above 200 ppm chloride or at temperatures of 38 °C or above. In seawater at 10 A m<sup>-2</sup>, the addition of Mo reduced the consumption rate from 0.22 to 0.15 kg A<sup>-1</sup> year<sup>-1</sup> at ambient temperatures and from 0.63 to 0.21 kg A<sup>-1</sup> year<sup>-1</sup> at 51 °C.<sup>15</sup> However, a considerably higher rate of 0.9 kg A<sup>-1</sup> year<sup>-1</sup> at 10.8 A m<sup>-2</sup> has been reported for molybdenum-containing silicon iron in chloride-containing waters.<sup>11</sup> Because the addition of Cr results in even greater improvements in performance, the molybdenum-enhanced alloy has been little used.

#### 4.20.2.4.3 *High-silicon-chromium iron*

High-silicon chromium iron alloy (HSCI) came into commercial use by about 1959.<sup>15</sup> The addition of chromium, together with silicon, results in a film that has a high resistance to pitting in waters containing halide ions and these alloys can, therefore, be used with confidence in seawater- or chloride-containing soils. A typical analysis is 14.5% Si, 0.75% Mn, 1.0% C, 4.5% Cr, and remainder Fe. In the United Kingdom, this anode is manufactured to BS 1591:1975, which permits a variation in silicon content from 14.25% to 15.25% and of chromium from 4.0% to 5.0%, with a maximum carbon content of 1.40%. The equivalent US standard is ASTM A 518-64 Grade 2 with a silicon content of 14.2–14.75% and a chromium content of 3.25–5.00%. Neglecting possible mechanical damage and anode/cable joint failure, it is possible, in view of the very minor pitting sustained in free suspension, for the

anode to continue operating until almost totally consumed. Note that HSCI anodes cannot be used in potable waters because of the possibility of chromium contamination.

Comparative tests of silicon iron and chromium-containing silicon iron in seawater at 93 °C and 10.8 A m<sup>-2</sup> produced consumption rates of 8.4 kg A<sup>-1</sup> year<sup>-1</sup> and 0.43 kg A<sup>-1</sup> year<sup>-1</sup>, respectively.<sup>16</sup> These figures show that in seawater the consumption rate of HSI without the addition of chromium may approach that of steel, but because of the very deep pitting experienced in chlorides, and the fragility of HSI, it is effectively inferior to steel. However, in fresh waters, HSI has a far lower corrosion rate than steel. The consumption rate of chromium-containing variety, freely suspended in seawater, increased from 0.33 kg A<sup>-1</sup> year<sup>-1</sup> at 10.8 A m<sup>-2</sup> to 0.48 kg A<sup>-1</sup> year<sup>-1</sup> at 53.8 A m<sup>-2</sup>. Direct burial in seawater silt or mud also increases the consumption rate, with value of 0.7 kg A<sup>-1</sup> year<sup>-1</sup> at 8.5 A m<sup>-2</sup> increasing to 0.94 kg A<sup>-1</sup> year<sup>-1</sup> at 23.4 A m<sup>-2</sup>.<sup>17</sup> A recent evaluation of HSCI anodes in different soil conditions has been conducted by Jakobs and Hewes.<sup>18</sup> They report a consumption rate for different HSCI alloys between 0.32 and 0.87 kg A<sup>-1</sup> year<sup>-1</sup> in 3% NaCl, at a current density of 21.5 A m<sup>-2</sup>, depending upon the alloy composition; while in soils containing 2% SO<sub>4</sub><sup>2-</sup>, consumption rates varied between 0.29 and 0.53 kg A<sup>-1</sup> year<sup>-1</sup>, again depending upon the alloy composition.

Improvements in anode construction have been carried out to reduce the nonuniform material loss along the length of the HSCI anode, the so-called ‘end effect’ phenomenon. This involves incorporating a taper in the anode casting at the connection end, or the use of hollow, centrifugally cast anodes of uniform wall thickness with a centrally located interior electrical connection.<sup>19</sup> Similar configurations are now used for HSI anodes. Cable connections for solid rod anodes use compression, cast lead, or taper pin connections, sealed by a combination of epoxy filling and heat shrinkable sleeves. Cylindrical anodes have centre connections with taper wedges or cast lead. Care must be taken to ensure that the cable insulation and sheathing are adequate for use in an oxidizing environment, in which chlorine evolution occurs. Kynar and high molecular weight polyethylene are commonly used.

#### 4.20.2.5 *Magnetite Anodes*

A compound, rather than an alloy, of iron, magnetite (Fe<sub>3</sub>O<sub>4</sub>) has been in use since the 1970s as a CP

anode, although its use as an anode material had been known for some time previously.<sup>20</sup> As an oxide, and being very brittle, it cannot be formed into an anode by conventional means. Magnetite has a melting point of 1540 °C and can be cast using special techniques and with the addition of certain alloying elements.<sup>21</sup> The anodes are in the form of a cast alloyed magnetite shell, the centre of which is hollow. The internal surfaces of the magnetite shell are then lined with an electronic conductor so as to ensure a uniform distribution of current density over the external surface. This technique overcomes the longitudinal current attenuation that would occur because of the relatively high resistivity of magnetite (3.3  $\Omega\text{m}$  quoted by Linder<sup>21</sup> and 0.8  $\Omega\text{m}$  by Kofstad).<sup>22</sup> Magnetite anodes can be operated at elevated temperatures up to 90 °C, with the limitation in temperature being failure of the anode cable connection and not the magnetite itself.

In early magnetite anodes, the internal lining consisted of a thin copper layer, but the poor electrical contact between the copper layer and the magnetite, together with the fact that the cable-to-anode connection was made at the anode head, resulted in a nonuniform current density on the external magnetite surface, which contributed, in part, to the poor performance reported for some of the early anodes. Subsequently, the manufacturers perfected a method of electrodepositing a lead alloy lining onto the internal magnetite surface with spring-loaded cable-to-anode connection made at the mid-point of the anode. Special care and some ingenuity in design are required in insulating the connection.

Magnetite anodes exhibit a relatively low consumption rate and can be used in seawater, freshwater, and soils. This low consumption rate enables a light-weight anode construction to be utilized. For example, the anode described by Linder<sup>21</sup> is 800 mm in length, 60 mm in diameter, 10-mm wall thickness, and 6 kg in weight. Tests carried out in seawater over the current density range 30–190  $\text{A m}^{-2}$  showed the consumption rate to be dependent upon current density, increasing from 1.4 to 4  $\text{g A}^{-1}\text{year}^{-1}$  over the current density range studied (with the recommendation that to achieve the required life, the current density should not exceed 115  $\text{A m}^{-2}$ ).<sup>23</sup> Later work by Jakobs and Hewes<sup>18</sup> indicated the consumption rate in seawater to be less than 1  $\text{g A}^{-1}\text{year}^{-1}$  at 21.6  $\text{A m}^{-2}$ , while at 32.4  $\text{A m}^{-2}$  a consumption rate of 12–41  $\text{g A}^{-1}\text{year}^{-1}$  was observed. Higher consumption rates were reported for magnetite anodes in soils containing 2%  $\text{SO}_4^{2-}$ ; namely 75  $\text{g A}^{-1}\text{year}^{-1}$

at current densities of 21.6 and 32.4  $\text{A m}^{-2}$ . Jakobs<sup>24</sup> also conducted a survey of different anode systems in soils and found magnetite anodes after 2 years' exposure and operating at a current density of 43  $\text{A m}^{-2}$  to be in good condition with little evidence of attack.

The main disadvantages of magnetite anodes are that they are brittle and susceptible to high-impact shocks, as is the case with silicon iron anodes, while some of the earlier anodes were subject to failure from thermal cycling.<sup>9,21</sup> Indeed, one evaluation of magnetite anodes reported a high incidence of failure,<sup>24</sup> and a more recent report<sup>25</sup> suggests an increased tendency to failure of magnetite anodes when compared with other, more conventional, anode materials. These failures were mainly associated with poor installation practice and operation at current densities in excess of the manufacturers' maximum recommended values (77  $\text{A m}^{-2}$  for seawater and 30  $\text{A m}^{-2}$  for soil). Improvements in design have now led to a more reliable anode with a decrease in the level of reported failures.<sup>26</sup>

Magnetite may also be used in combination with lead or electrodeposited onto a titanium substrate.<sup>27</sup> The latter anode system has been shown to exhibit good operating characteristics in seawater but at present it is only of academic interest showing no benefit over platinized and mixed metal oxide anodes.

#### 4.20.2.6 Ferrite Anodes

Sintered and sprayed ceramic anodes have been developed for CP applications. The ceramic anodes are composed of a group of materials classified as ferrites with iron oxide as the principal component. The electrochemical properties of divalent metal oxide ferrites in the composition range around 0.1MO–0.9 $\text{Fe}_2\text{O}_3$ , where M represents a divalent metal, for example, Mg, Zn, Mn, Co, or Ni, have been examined by Wakabayashi and Akoi.<sup>28</sup> They found that nickel ferrite exhibited the lowest consumption rate in 3% NaCl (of 1.56  $\text{g A}^{-1}\text{year}^{-1}$  at 500  $\text{A m}^{-2}$ ) and that an increase in the NiO content to 40 mol%, that is, 0.4NiO–0.6 $\text{Fe}_2\text{O}_3$  reduced the dissolution rate to 0.4  $\text{g A}^{-1}\text{year}^{-1}$  at the expense of an increase in resistivity from 0.02 to 0.3  $\Omega\text{cm}$ .

Ceramic anodes may be cast or sintered around a central steel core which acts as the electrical conductor. However, anodes produced in this form are brittle and susceptible to mechanical shock. Ceramic anodes based on a plasma-sprayed ferrite coating on a titanium or niobium substrate have also been developed. These consist of plasma-sprayed

lithium, nickel, or cobalt ferrite on a machined Ti or Nb button-shaped substrate fitted into a plastic electrode holder.<sup>29</sup> This method of anode construction is durable and not as prone to mechanical damage as the sintered ceramic anode, while the ceramic coating is abrasion resistant and has a long operational life. Kumar *et al.*<sup>29</sup> report a dissolution rate for a sprayed lithium ferrite of  $1.7 \text{ g A}^{-1} \text{ year}^{-1}$  at a current density of  $2000 \text{ A m}^{-2}$  in seawater. The anode exhibited good performance with no damage on the ceramic coating observed during a two-month trial. However, the normal restrictions on operating voltages for titanium electrodes (discussed below) were still found to apply, with pitting<sup>30</sup> of the titanium substrate reported at 9.66 V versus SCE.

## 4.20.3 Lead-Based Materials

### 4.20.3.1 Lead Alloys

Investigations into the use of lead and lead alloys for CP were carried out in the early 1950s<sup>31–33</sup> and a practical material had been developed by 1954. The general use of lead alloys in seawater had previously been established.<sup>34,35</sup> The anodic behavior of lead varies depending upon the electrolyte composition and the electrode potential and has been the subject of a number of reviews.<sup>9,35,36</sup> In  $\text{NO}_3^-$ ,  $\text{CH}_3\text{COO}^-$ , and  $\text{BF}_4^{2-}$  solutions, lead will form highly soluble salts, while in  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  solutions, insoluble salts are formed.

The use of lead as an anode depends on the formation and maintenance of a hard layer of lead oxide,  $\text{PbO}_2$ . The  $\text{PbO}_2$  acts as an inert anode, with the lead acting both as a source of  $\text{PbO}_2$  and an electrical conductor.  $\text{PbO}_2$  is relatively insoluble in seawater and its dissipation is more usually associated with mechanical wear and stress than electrochemical action. In alkaline solutions approaching pH 10,  $\text{PbO}_2$  dissolves and for this reason lead anodes should be mounted clear of cathodic areas, where alkalinity will form. It should be noted that lead dioxide will discharge if electronically connected to a more base material, when in an unenergized state, with the consequent formation of lead chloride and corrosion of the anode.

Lead alloys have found considerable use as anodes in a wide variety of electrochemical applications, with studies dating back to 1924.<sup>36–38</sup> Pure lead has been tried as an anode in seawater and shown to be unsuitable, because of the formation of  $\text{PbCl}_2$  beneath the  $\text{PbO}_2$  which insulates the  $\text{PbO}_2$  from the substrate. The anodic behavior of lead in  $\text{Cl}^-$

solutions depends upon  $\text{Cl}^-$  ion concentration, solution pH, and the presence of passivating anions such as  $\text{CO}_3^{2-}$ ,  $\text{HCO}_3^-$ , and  $\text{SO}_4^{2-}$ . At low current densities and low  $\text{Cl}^-$  concentration, dissolution of Pb will occur and a  $\text{PbCl}_2$  deposit will not be formed at the anode. In high  $\text{Cl}^-$  concentrations and at high current densities, the rate of formation of  $\text{Pb}^{2+}$  will be high enough for the solubility product for  $\text{PbCl}_2$  to be exceeded and  $\text{PbCl}_2$ , not  $\text{PbO}_2$ , will be deposited at the anode. The formation of a  $\text{PbO}_2$  coating on lead, when it is anodically polarized in  $\text{Cl}^-$ , is achieved more readily by alloying lead with silver or other metals or by incorporating inert conducting micro-electrodes on the Pb surface.

Lead alloys have been investigated to determine their suitability as anodes for CP. Tests<sup>39</sup> were carried out on lead–silver alloys and found that Pb–1%Ag was suitable for use in seawater provided that the current density did not exceed  $100\text{--}200 \text{ A m}^{-2}$ , as at higher current densities an insulating film formed. Morgan<sup>39,40</sup> found that Pb–6Sb–1Ag alloy gave a lower consumption rate and exhibited a harder  $\text{PbO}_2$  film than Pb–6Sb or Pb–1Ag. Pb–6Sb–2Ag alloys are slightly better, but ~50% more expensive. Other work<sup>41</sup> has also shown that additions of Mn to Pb–2Ag alloys may have a beneficial effect on anode performance in seawater. The Pb–6Sb–1Ag alloy is commonly used where lead–silver anodes are specified. The results of tests on Pb–6Sb–1Ag given in **Table 1** are of interest in recognizing the scope for the use of lead alloys in waters of differing resistivity.

Additions of antimony, bismuth, and tin to the lead appear to be detrimental for anode applications. Dispersion-hardened lead alloys have been unsatisfactory, showing pronounced spalling in the direction of extrusion. There is an indication that the addition of 0.1% Ag is almost as effective as 1% and additions as low as 0.01% that have been utilized in practice. Pb–0.1Te–0.1Ag has been also used with apparent success.<sup>42</sup>

In electrolytes containing sulfate and chloride ions, the sulfate ion favors the formation of lead sulfate which is rapidly transformed to lead dioxide. The continuing satisfactory operation of the anode depends upon the initial conditions of polarization. In solutions containing higher sulfate concentrations, or when the water is agitated, the lead dioxide is of better quality and more adherent when formed below  $108 \text{ A m}^{-2}$ .<sup>43</sup>

It is important to realize that a minimum current density is necessary to ensure the passivation of lead–silver anodes and that anodes operating below this

current density may experience rapid consumption rates. A minimum value of  $32.3 \text{ A m}^{-2}$  is quoted by Barnard *et al.*<sup>34</sup> The consumption rate of lead-silver is high in the initial stages of operation as can be seen from Table 1. However, the rate in seawater, over an extended period, is generally taken as  $0.06 \text{ kg A}^{-1} \text{ year}^{-1}$ . If a lead alloy is used as a ship's hull anode, consideration should be given both to the make-up of the water in which the anode is initially passivated and that in which it will normally operate. The same consideration will apply for static structures in estuarine waters.

Experience with Pb-6Sb-1Ag (and Pb/Pt) anodes operating in seawater at depths greater than 25 m has revealed a marked increase in consumption rate compared with that found on the surface. Hollandsworth and Littauer<sup>44</sup> have calculated that on a fully formed anode at  $400 \text{ A m}^{-2}$ , only  $6 \times 10^{-5}\%$  of the current is used to maintain the passive film, but at a depth of 180 m, this percentage increases to  $2 \times 10^{-3}\%$  and results in a 30-fold increase in consumption rate. They propose that a combination of the mechanical forces acting on the  $\text{PbO}_2$  at increased depths and the reduction in the evolution of chlorine are responsible for the increased consumption rate. It is, therefore, recommended that lead anodes are not used at depths below 25 m.

**Table 1** Behaviour of Pb-6Sb-1Ag anodes

Resistivity of electrolyte at 35°C ( $\Omega\text{m}$ )	Average wastage rate at $108 \text{ A m}^{-2}$ ( $\text{kg A}^{-1} \text{ year}^{-1}$ )	Length of trial (days)	Note
0.163 (sea)	0.086	236	1
0.163 (NaCl)	1.99	1-75	2
0.5 (sea)	0.0145	234	1
0.5 (NaCl)	0.654	1-75	3
10 (sea)	23.80	5-75	4
10 (NaCl)	23.70	1-75	4
50 (sea)	0.10	236	5
50 (NaCl)	11.64	1-75	5

Notes:

1. Service indicates a practical consumption of between  $0.057$  and  $0.114 \text{ kg A}^{-1} \text{ year}^{-1}$ . Under laboratory conditions,  $\text{PbO}_2$  has been formed at current densities as low as  $21.6 \text{ A m}^{-2}$ . Typical operating current densities are  $54\text{--}270 \text{ A m}^{-2}$  at wastage rates of  $0.045$  to  $0.082 \text{ kg A}^{-1} \text{ year}^{-1}$ .
2. Similar performance between  $0.7$  and  $270 \text{ A m}^{-2}$ : formation of this adherent film of  $\text{PbO}_2$ .
3. Similar performance between  $2.7$  and  $160 \text{ A m}^{-2}$ ; thick nodules of  $\text{PbO}_2$  in some areas; severe deterioration at  $270 \text{ A m}^{-2}$ .
4. Tests have indicated failure to form  $\text{PbO}_2$ ; rapid deterioration, although at  $100 \text{ A m}^{-2}$  it shows down after several weeks. Increasing silver content results in some improvement. Anode passivated in  $0.163 \text{ ohm m}$  water continues to operate whilst  $\text{PbO}_2$  is undamaged.
5. Above  $22 \text{ A m}^{-2}$ , deterioration rate may be low, but  $\text{PbO}_2$  coating is poor and interspersed with  $\text{PbCl}_2$ .

### 4.20.3.2 Lead/Platinum Bielectrodes

The insertion of platinum microelectrodes into the surface of lead and some lead alloys has been found to promote the formation of lead dioxide in chloride solutions.<sup>45,46</sup> Experiments with silver and titanium microelectrodes have shown that these do not result in improvement.<sup>42</sup> Similar results to those when using platinum have been found with graphite and iridium, and although only a very small total surface area of microelectrodes is required to achieve benefit, the larger the ratio of platinum to lead surface, the faster the rate of formation of the oxide layer.<sup>44</sup> Platinized titanium microelectrodes have also been utilized.

Lead dioxide will readily form on lead with a platinum electrode as small as  $0.076 \text{ mm}$  in diameter.<sup>44,45,47</sup> It has been observed that the current density on the platinum is considerably less than that on the lead dioxide once polarization has been achieved, the proportion of current discharged from the platinum decreasing with increase in total current. A typical anode for practical use would be in the order of  $25\text{--}48 \text{ mm}$  in diameter, with hard platinum alloy pins of  $0.50\text{-mm}$  diameter by  $10\text{-mm}$  length, spaced every  $150\text{--}300 \text{ mm}$  and progressively positioned around the circumference.<sup>48</sup> The pins are a press fit into holes in the lead or lead alloy and lie flush with the surface. The lead is peened around the pins to improve mechanical and electrical contact.

The action of platinum microelectrodes has been extensively studied.<sup>9,36</sup> Trials carried out by Peplow<sup>49</sup> have shown that lead/platinum bielectrodes can be used in high velocity seawater at current densities up to  $2000 \text{ A m}^{-2}$  and that blister formation with corrosion under the blisters is decreased by the presence of platinum microelectrodes. The current density range in which the anode is normally operated is  $200\text{--}750 \text{ A m}^{-2}$  with the maximum working current density quoted as  $1000 \text{ A m}^{-2}$ . The consumption rate of these anodes ranged from  $0.0014$  to  $0.002 \text{ kg A}^{-1} \text{ year}^{-1}$  at  $500 \text{ A m}^{-2}$ , but increased to  $0.003 \text{ kg A}^{-1} \text{ year}^{-1}$  at  $2000 \text{ A m}^{-2}$ .<sup>49</sup> The results of work in this field<sup>44,47,50,51</sup> can be summarized as follows:

- Pt acts as a stable electrode for nucleation of  $\text{PbO}_2$  and limits  $\text{PbCl}_2$  formation.
- In the case of a lead anode (without a platinum microelectrode), the  $\text{PbO}_2$  thickens during prolonged polarization with the consequent development of stresses in the film.
- The stresses result in microcracks in the  $\text{PbO}_2$ , thus, exposing the underlying lead, which corrodes with the formation of voluminous  $\text{PbCl}_2$ , resulting

in blisters; the resistance of the anode increases and high voltages are required to maintain the current (if the voltage is maintained constant the current falls to a low value).

- The platinum microelectrode appears to act as a potentiostat and maintains the potential of the lead–solution interface at any crack at a value that favors the reformation of  $\text{PbO}_2$ , rather than the continuous formation of  $\text{PbCl}_2$ , which would otherwise result in excessive corrosion.

It is known that an increase in the resistance of a lead electrode indicates that corrosion is taking place with the formation of an insulating film of a lead compound and this is confirmed in practice by observation of the anodes, which reveal localized areas coated with white corrosion products, although the  $\text{PbO}_2$  remains intact at other areas. However, it is possible that an insulating film forms over the whole surface, thus, isolating the conducting  $\text{PbO}_2$  from the lead. Wheeler<sup>52</sup> suggested that the sole function of the platinum is to provide a conducting bridge between the lead and the  $\text{PbO}_2$ . It has been demonstrated that, although initially the  $\text{PbO}_2$  nucleates at the surface of the platinum, the initially formed  $\text{PbCl}_2$  is rapidly converted into the  $\text{PbO}_2$  that is in direct contact with the lead.<sup>44</sup>

The formation of  $\text{PbO}_2$  is favored in the solutions containing passivating anions such as  $\text{SO}_4^{2-}$  and in the chloride solutions of intermediate concentrations; very high and very low concentrations of chloride inhibit the formation of  $\text{PbO}_2$ . The platinum/lead bielectrode performs best in seawater and is not recommended for use in waters of high resistivity.

#### 4.20.3.3 Lead/Magnetite Composites

It has been demonstrated that the particles of magnetite in a lead matrix can produce results similar to those produced by platinum, acting as stable nucleation sites for  $\text{PbO}_2$  formation.<sup>53</sup> Composite Pb/ $\text{Fe}_3\text{O}_4$  anodes containing 10, 15, and 20%  $\text{Fe}_3\text{O}_4$  were prepared by mixing powders of the constituents (Pb 30–60 mesh,  $\text{Fe}_3\text{O}_4$  72 mesh) and compacting at a pressure of 300 MPa.<sup>9,54</sup> These anodes were found to operate successfully in both artificial seawater (resistivity  $0.25 \Omega \text{ m}$ ) and in the same water diluted with distilled water to give a higher resistivity of  $10 \Omega \text{ m}$ .

In seawater, the anodes were found to operate best in the current density range  $100\text{--}1000 \text{ A m}^{-2}$ , a weight loss of  $50 \text{ g A}^{-1} \text{ year}^{-1}$  being recorded for a 20% composite anode at  $300 \text{ A m}^{-2}$ . No initial rise

in voltage at a constant current density was observed, as is the case with Pb/Pt electrodes, where the potential increases because of the formation of  $\text{PbCl}_2$ . The steady-state potential of the anode was found to be dependent upon the  $\text{Fe}_3\text{O}_4$  content. In freshwater solutions, the composite Pb–10%  $\text{Fe}_3\text{O}_4$  anodes were also able to form a  $\text{PbO}_2$  film, although an induction period was necessary before stabilization was complete. Hill reports that at current densities less than  $150 \text{ A m}^{-2}$ , the anodes were unable to stabilize. Consumption rates similar to those in artificial seawater were reported for the Pb–20%  $\text{Fe}_3\text{O}_4$  composites, which were found to give the optimum performance. However, in tapwater with a high  $\text{SO}_4^{2-}$  and  $\text{CO}_3^{2-}$  concentration and low  $\text{Cl}^-$  concentration (36 ppm), a consumption rate of  $100 \text{ g A}^{-1} \text{ year}^{-1}$  was recorded.

#### 4.20.3.4 Lead Dioxide on other Substrates

Lead dioxide on graphite or titanium substrates has been utilized as an anode in the production of chlorate and hypochlorites<sup>55</sup> and on nickel as an anode in lead–acid primary batteries.<sup>56</sup> Lead dioxide on a titanium substrate has also been tested for use in the CP of heat exchangers<sup>11</sup> and in seawater may be operated at current densities up to  $1000 \text{ A m}^{-2}$ .<sup>57</sup> However, this anode has not gained general acceptance as a CP anode for seawater applications, as platinized Ti anodes are more robust.

### 4.20.4 Carbonaceous Materials

#### 4.20.4.1 Graphite

Graphite is the dense, crystalline, form of carbon. Graphite anodes are prepared by heating calcined petroleum coke particles with a coal tar pitch binder. The mix is then shaped as required and heated to  $\sim 2800^\circ\text{C}$  to convert the amorphous carbon to graphite.<sup>58</sup> Graphite is used in preference to amorphous carbon as it is a less porous and more reliable anode material, particularly in saline conditions. It is current practice to impregnate the graphite, traditionally with linseed oil, although synthetic resins are also successful. The concept behind impregnation is to reduce the porosity and hence inhibit subsurface gas evolution or carbon oxidation which would initiate spalling and early anode failure. Being a natural lubricant, the material can easily be machined. It has a negligible contact resistance and it is relatively simple to make a sound cable joint. It can be DC

welded under high pressure argon. It is brittle but a little more shock resistant than silicon iron, in that it can absorb energy by localized damage, and it is a much lighter material to handle. Cable-to-anode joints need to be designed and made with the same care as those for high-silicon iron anodes.

The performance of graphite in seawater, where chlorine is the principal gas evolved, is considerably better than that in fresh water where oxygen is produced. Graphite is effectively immune to chlorine and has a long history in the chemical industry in this and similar applications.<sup>59</sup> In freshwater applications, considerable amounts of free oxygen are produced at the anode surface, which can attack both the carbon and any organic binders used to reduce porosity, resulting in a high consumption rate. The corrosion product is predominantly carbon dioxide. For this reason, graphite anodes for underground service are used in conjunction with a carbonaceous backfill.

If all the oxygen produced were to combine with the carbon, the maximum theoretical consumption rate would be of the order of  $1 \text{ kg A}^{-1} \text{ year}^{-1}$ .<sup>60</sup> However, in practice, the rate is usually of the order of  $0.2 \text{ kg A}^{-1} \text{ year}^{-1}$  and in coke breeze may be as low as  $0.05 \text{ kg A}^{-1} \text{ year}^{-1}$ . In seawater, where chlorine is the predominant gas produced, any oxygen formed will be quickly removed and the corrosion rate may be very low. Electrode reactions occur to a depth of 0.5 mm below the surface of the anode and the true current density can be shown to be only 1/400th of the value indicated by the superficial geometrical area.<sup>61</sup> Acidity has been found to increase the consumption rate,<sup>62</sup> as has the presence of sulfate ions.<sup>63</sup> Interestingly, when buried in soils containing 2%  $\text{SO}_4^{2-}$  Jakobs and Hewes<sup>18</sup> report the graphite consumption rates of  $1.56 \text{ kg A}^{-1} \text{ year}^{-1}$  at  $21.6 \text{ A m}^{-2}$ , which is considerably higher than the theoretical maximum consumption rate.

The anode is not recommended for use in water at above  $50^\circ\text{C}$ , where the consumption rate increases rapidly and erratically. It is no longer the practice to use this material in cooling water plants where a secondary attack from contact with the relatively noble pieces of anode may occur, should pieces break off the anode.

**Table 2** gives some results obtained with graphite under different conditions. Results obtained with one particular installation using a 100 mm diameter anode of 1 m length operating at  $6.9 \text{ A m}^{-2}$  indicate a predicted life of 20 years.<sup>64</sup>

Graphite anodes, when used in soils, are invariably placed in a carbonaceous backfill. This helps

**Table 2** Performance of graphite anodes

<i>Environment</i>	<i>Wastage rate (<math>\text{kg A}^{-1} \text{ year}^{-1}</math>)</i>	<i>Current density (<math>\text{A m}^{-2}</math>)</i>
Backfill	0.9	10.8
Hot water	0.9	
<b>Seawater</b>	<b>0.045</b>	<b>4.5–115</b>
Seawater	Little	10.8
Fresh water	0.45	3.5
Fresh water	0.45	2.7
Mud	0.91–1.36	71

Data reproduced from corresponding article in 3rd Edition of Shreir's Corrosion.

compensate for the lower electrical resistivity of graphite when compared with silicon iron. In such an environment, no build-up of a film of high resistance between the anode and backfill occurs, unlike silicon-iron anodes where the resistance can increase with time.<sup>65</sup>

Failures of graphite anodes can occur by corrosion of the anode connection, high current densities at either end of the anode resulting in excessive consumption rates often referred to as 'end effect' corrosion, sealant failure, or surface contamination.

#### 4.20.4.2 Carbonaceous Backfills

Carbonaceous backfill, either coke breeze, or, more recently, calcined petroleum coke, is used to surround a buried solid anode, or anodes, to produce an anode groundbed with an increased surface area, thus, significantly lowering the resistance to the surrounding environment. Groundbeds may be horizontal, vertical, or deep-well in form, depending on the soil resistivity in which they are installed. Such backfills have been used in conjunction with a number of different 'primary' anodes, including silicon iron, graphite, platinized titanium, and mixed metal oxide coated titanium. Canister anodes consist of a spirally wound galvanized steel outer casing containing a pre-packed carbonaceous backfill which surrounds the primary anode element which may be graphite, silicon iron, platinized titanium, mixed metal oxide-coated titanium, or platinized niobium. Such anodes allow ease of installation and are often used as shallow vertical linear arrays.

By using carbonaceous backfill, the consumption of the primary anode is reduced, as the majority of the conduction from the anode to the backfill becomes electronic rather than electrolytic. The electrochemical and physical nature of the backfill results in the spread of the anode reaction (formation of  $\text{CO}_2$  and  $\text{O}_2$ , or  $\text{Cl}_2$ )

over a large surface area, thereby reducing attack on the primary anode. The coke is slowly oxidized, primarily to carbon dioxide, which in a suitably vented groundbed will escape into the atmosphere together with any oxygen or chlorine formed. If all the oxygen reacted with the carbon, consumption would be  $1.02 \text{ kg A}^{-1} \text{ year}^{-1}$ , but in practice the rate is of the order of  $0.25 \text{ kg A}^{-1} \text{ year}^{-1}$ ,<sup>65</sup> depending upon the environment.

Some typical properties of coke breeze and similar materials are shown in **Tables 3–5**. The densities given in **Table 3** are for bulk material and are dependent upon grading. Flake graphite is not recommended

**Table 3** Densities of carbonaceous backfill

<i>Backfill in bulk</i>	<i>Density range (<math>\text{kg m}^{-3}</math>)</i>	<i>Typical density (<math>\text{kg m}^{-3}</math>)</i>
Coal coke breeze	650–800	690
Calcined petroleum coke granules	700–1100	720–850
Natural graphite granules	1100–1300	–
Man-made graphite, crushed	1100–1300	–

Data reproduced from corresponding article in 3rd Edition of Shreir's Corrosion.

**Table 4** Typical coal coke specification for CP

To pass 16-mm screen	100%
To pass between 16-mm and 8-mm screen	8.9–9.8%
To pass between 8-mm and 1-mm screen	78–90%
To pass 1-mm screen	1–14%
Fixed carbon	82.7 min to 91% max
Volatile matter	0.1%
Ash	8.6%
Moisture	5% max, typically 4%
Sulfur	1.2% max, typically
Phosphorus	0.42–0.7%
Resistivity (uncompacted)	0.55 $\Omega\text{m}$ max, (typically 0.35 $\Omega\text{m}$ )
Specific gravity	1.4

for use in groundbeds as it tends to conglomerate and prevent gas emission.

The grading of the coke is of some importance in that too large a particle size offers large local contact resistance, leading to uneven consumption, while an excessively fine material leads to over-tight compaction and resultant gas blocking (gaseous polarization). Chemicals are sometimes added, for example, calcium hydroxide (5–10 wt%), to counteract the tendency to lose moisture by electroosmosis, as it is essential that an aqueous electrolyte is present to replace water consumed in the anodic reaction and conduct the current to the protected structure. The alkaline material also serves to neutralize anodically formed acid. Calcium sulfate is sometimes used in very dry conditions. A typical specification for coke suitable for CP groundbed use is given in **Table 4**.

The coke breeze is tamped down at a minimum pressure of 15 Pa. This ensures integrity of the groundbed while in operation and allows for the reduction in volume produced by chemical oxidation. A pressure of this magnitude will also reduce the initial bulk resistivity of the coke. In practice, resistivities between 0.08 and 0.29  $\Omega\text{m}$  have been recorded on coke samples used in typical groundbeds. The effect of pressure on the measured value for resistivity of different coke samples has also been reported elsewhere.<sup>66</sup> The resistivity of bulk metallurgical coke is given as 0.024  $\Omega\text{m}$  with a slightly lower value of 0.020  $\Omega\text{m}$  at a pressure of 0.43 Pa, while for calcined fluid petroleum coke at zero applied pressure the resistivity was 0.02  $\Omega\text{m}$ , which decreased to 0.002  $\Omega\text{m}$  when tested at an applied pressure of 1.31 MPa.

The backfill cross-section, in a typical horizontal groundbed, is normally  $\sim 300 \times 300 \text{ mm}$ . Deep-well groundbeds have a diameter of 150–300 mm. Bed length depends upon the required current output and the surrounding soil resistivity. In freshwater soil conditions, higher than average current density at the ends of the primary anodes can be prevented by not exceeding a primary anode spacing of twice its length. As the electrolyte resistance decreases, with a consequent increase in current density at the ends of the primary anodes, either a reduction in anode spacing or an increase in backfill cross-section should be considered.

Calcined petroleum coke breeze is often used in deep-well applications. The material has a low particle size and, with suitable additives, may be converted into a slurry and pumped into a borehole. The sulfur content of this material is high (1.4%), but moisture

(0.2%), ash (0.4%), and volatiles (0.4%) are low. The typical resistivity of this material is  $0.15 \Omega\text{m}$ . A petroleum coke with spherical grains is available, specifically for borehole CP applications.<sup>67</sup> The round grains ensure high bed porosity and enable gas to escape, allowing the coke to sink to the base of the borehole. The resistivity of this material is quoted as  $0.1 \Omega\text{m}$ .

#### 4.20.4.3 Conductive Polymers

A continuous carbon loaded polymer anode system has been developed specifically for the CP of buried pipelines and tanks. The anode, marketed under the trade name AnodeFlex,<sup>68</sup> consists of a continuous stranded copper conductor (6AWG), which is encased in a thick jacket of carbon-loaded polymer, with overall diameter of 12.5 mm. To prevent unintentional short circuits an insulating braid is sometimes applied to the outer surface of the conductive polymer. The anode may be operated in the temperature range  $-18$ – $65^\circ\text{C}$  and at currents up to 0.05 A per linear meter in soil and 0.01 A per linear meter in water, which corresponds to effective maximum surface current densities of  $0.66 \text{ A m}^{-2}$  in soil and  $0.13 \text{ A m}^{-2}$  in water. No precise details on the anode consumption rate have been provided by the manufacturer, but as the active component is carbon, the consumption rate would be expected to be of a similar order to that exhibited by graphite anodes. The anode may be installed in conventional groundbeds or laid in close proximity to the cathode, for example, parallel to a pipeline route. The anode may be buried either directly in soil or in carbonaceous backfill. The intended applications for this material are external tank base protection, internal vessel protection, mitigation of poor current distribution, and to supplement conventional CP systems by providing increased levels of CP in underprotected areas.

The disadvantage of this anode system for the CP of pipelines is that the anode length provided is by one single connection to the DC. Power source is limited by resistive losses along the copper conductors. Thus, the required current output per unit length and soil resistivity are limiting factors and a number of anode connections may be required to protect long lengths of pipeline. The anode has a poor chemical resistance to oils and should not be used in situations where oil spillage may occur.

A similar conductive polymer electrode has been designed specifically for the CP of steel reinforcing bars in concrete and has been marketed under the

trade name Ferex.<sup>69</sup> The anode consists of a 16AWG stranded copper conductor surrounded by a carbon-loaded polymeric coating similar to that used on the AnodeFlex system<sup>68</sup> to provide a nominal anode diameter of 8 mm.<sup>70</sup> The manufacturer claims that at a maximum recommended current density of  $0.08 \text{ A m}^{-2}$  the anode life in concrete will be 32 years with a proportionately longer life at lower current densities. The anode is fixed to the concrete using nonmetallic fixings and may be supplied as a prefabricated mesh or more often as a continuous anode strand which is laid over the surface of the structure to be protected. The spacing between the anode strands may be adjusted to give the required current distribution and current density per unit area of concrete necessary to provide CP to a particular structure. A number of anode connections are made to the DC power source using proprietary splice kits (approximately one for every  $60$ – $80 \text{ m}^2$  of concrete to be protected). This will provide redundancy for anode failure and reduce resistive losses along the anode cable. Care must also be taken not to expose the copper conductor during installation or anode failure will take place. Once fitted to the concrete surface, a 15-mm thick cementitious overlay (gunite) is applied above the anode mesh, as recommended by the anode manufacturer, although thicknesses of up to 35–40 mm have been applied in some instances.

The major electrochemical reactions at the anode surface are oxygen and chlorine evolution coupled with oxidation of the active carbon to carbon dioxide. Eventually, all the carbon is removed from the anode coating and this allows perforation of the copper conductor leading to ultimate anode failure. Failures due to delamination of the concrete overlay coating have been reported in the United States, but have not been observed to any significant extent in Europe,<sup>71</sup> although some early failures of the anode system have been associated with high local current densities in areas of low concrete cover and high moisture or salt content.<sup>72</sup> The major application of this anode system is, therefore, on structures that are relatively dry with a uniform current requirement.

#### 4.20.4.4 Conductive Overlay Systems

Early systems used for the protection of reinforced concrete bridge decks were on the basis of the use of a continuous layer of coke breeze/asphaltic cement (85%/15%) to ensure uniform current distribution.<sup>73</sup> Electrical connection was made using silicon iron anodes held in position using a nonconductive

epoxy and covered with a conductive cement. Fromm<sup>74</sup> investigated the performance of different coke breeze/asphalt mixes and developed a mix containing only 45% coke breeze which had a resistivity of  $0.03 \Omega \text{ m}$  and a void content of 5%. This was reported to give good results. The conductive mix was applied over the primary anodes, either silicon iron or graphite, to a total thickness of 50 mm and then given a protective top coat.

Schutt<sup>75</sup> reported that the coke breeze specification and conditions in which the mix is prepared are important factors in determining the optimum operation of such overlay systems, while further details on the coke breeze asphalt mix composition are given by Anderson.<sup>76</sup> Conductive concrete mixes with a polymer binder have also been developed as an anode system specifically for reinforced concrete CP systems.<sup>77</sup>

Conductive overlay systems are not practical propositions on vertical surfaces or surfaces where weight restrictions are important. However, they are proven CP systems and can be considered in conjunction with other reinforced concrete CP system anodes.

#### 4.20.4.5 Conductive Paints

Carbon loaded conductive coatings may be used for the CP of steel reinforcing bars in concrete. They are always used in conjunction with a primary anode material, for example, a platinized-niobium or platinized-titanium wire or a conductive polymer rod. Brown and Fessler<sup>78</sup> have conducted a laboratory evaluation of conductive mastics that can be brushed or sprayed onto the concrete surface to achieve the necessary thickness. However, the most extensive study on conductive paints for CP purposes was undertaken by the US Federal Highway Authority.<sup>77</sup> Nine commercially available resins were evaluated in this work. It was shown that neither thermal cycling, freeze thawing nor the application of CP currents resulted in any deterioration of the most successful paint system, now referred to as DAC-85, a solvent-based acrylic mastic containing graphite. Minor failures with this system have been reported but only in localized areas with a high chloride content. The anode system generally consists of platinized titanium or niobium wire laid in strips with the layers of carbon fiber interleaved between the strips. The paint is then mixed and applied on site. The paint consists of blends of resin and fine particles of coke. The performance of some paint systems is poor

because of attempts to operate the anodes at currents in excess of  $0.1 \text{ A m}^{-2}$ .

The advantages of conductive paints are that they are easy to apply and a concrete overlay is not required. They can be applied to complex shapes and are not a problem where weight restrictions are imposed.

### 4.20.5 Platinum Anodes

#### 4.20.5.1 Platinum

The properties of platinum as an inert electrode in a variety of electrolytic processes are well known, and in CP, it is utilized as a thin coating on a suitable substrate. In this way, a small mass of Pt can provide a very large surface area, and thus, anodes of this type can be operated at high current densities in certain electrolyte solutions, such as seawater, and can be economical to use. When platinum is made the anode in an aqueous solution, a protective electron-conducting oxide film is formed. Once this film has formed, current flow then occurs by oxygen evolution. In chloride-containing solutions, evolution of chlorine will also occur and is usually the predominant anodic reaction even at low chloride concentrations, for example, brackish waters. The relative proportions of oxygen and chlorine evolved will be dependent upon the chloride concentration, solution pH, anode potential, degree of agitation and nature of the electrode surface, with only a fraction of the current being used to maintain the passive platinum oxide film.<sup>79</sup> This results in a very low platinum consumption rate.

The dissolution rate of solid rods of high purity platinum over the current density range  $1180\text{--}4600 \text{ A m}^{-2}$  has been investigated. Values of  $17.5\text{--}26.3 \text{ mg A}^{-1} \text{ year}^{-1}$  were reported over the first year, but the rate decreased to a limiting value of  $2.6\text{--}4.4 \text{ mg A}^{-1} \text{ year}^{-1}$  over a 5-year period.<sup>80</sup> The high initial rate was attributed to preferential dissolution at grain boundaries and other high free energy sites. Tests carried out in the United Kingdom<sup>81,82</sup> on electrodeposited platinum on a titanium substrate indicate a consumption rate in seawater of  $8.8 \text{ mg A}^{-1} \text{ year}^{-1}$ , although values of up to  $15 \text{ mg A}^{-1} \text{ year}^{-1}$  have been quoted elsewhere.<sup>83</sup>

#### 4.20.5.2 Platinized Titanium

Titanium, which has been in commercial production since 1950,<sup>84</sup> is thermodynamically a very reactive metal, but has a strong tendency to passivate, that is, to form a highly stable oxide film which, although

only a few atoms thick, is highly protective in most natural environments. When made anodic in a chloride-containing solution, this anodic film thickens with increase in voltage, remaining protective until a potential of  $\sim 8$  V is reached, at which point localized film breakdown occurs with subsequent pitting. Until pitting occurs, the resistive nature of the oxide film prevents significant current, making titanium itself unsuitable for use as an anode material. However, this inertness makes titanium an eminently suitable substrate for platinum, which may be applied to the metal in the form of a thin coating. The presence of platinum allows electronic conduction across the oxide, with the resultant composite behaving in a similar manner to solid platinum. Any titanium exposed at discontinuities in the platinum layer remains protected by the anodically formed oxide film, provided surface potentials are maintained below  $\sim 8$  V. Platinized titanium, therefore, provides an economical method of utilizing the inertness and electronic conductivity of platinum on a relatively inexpensive, yet inert substrate.

Titanium can be forged, bent, cut, stamped, rolled, extruded, and successfully welded under argon, making possible a large variety of electrode shapes, that is, rod, sheet, tube, wire, or mesh. It is a very light yet strong material with a high resistance to abrasion. Cotton<sup>85,86</sup> was the first to publish results on platinized titanium as an anode material and the first commercial installation utilizing platinum plated titanium anodes was completed in 1958 at Thameshaven for the protection of a large shipping jetty.

Platinized titanium anodes are usually produced by the electrodeposition of a thin coating of platinum from aqueous solutions<sup>9</sup> on to chemically etched titanium. Warne<sup>87</sup> states that electrodepositing coatings from aqueous plating solutions have the advantage that control of thickness is easily achieved, irregularly shaped substrates can be plated, and the electrodeposited coatings are hard and abrasion resistant, by virtue of interstitial hydrogen codeposited in the plating process. Titanium is a very difficult metal to electroplate because of the presence of the oxide film. Sophisticated pretreatments with acids are necessary to remove the oxide film and achieve good adhesion. Improvements in the level of adhesion can be obtained by heat treatment after plating.<sup>88</sup>

From aqueous solutions, platinum can only be applied as a relatively thin porous layer. Although the porosity decreases with increase in deposit thickness, so does the internal stress and if the platinum adhesion is poor, the coating may exfoliate. As a

consequence, platinum thicknesses of 2.5–7.5  $\mu\text{m}$  are normally used, although it is possible with care to apply coatings of 12.5  $\mu\text{m}$  in one operation and still achieve good adhesion.<sup>79</sup> However, 7.5  $\mu\text{m}$  is generally considered the maximum thickness from one plating operation. Thicker deposits may be obtained by deposition in a number of stages, with interstage anneals to expel codeposited hydrogen and relieve internal stresses.

Platinum electrodeposits may also be produced from molten salt electrolytes. The high temperature process has the advantage that the deposits are diffusion bonded to the titanium substrate and, thus, have good adhesion; if necessary, thick deposits can be produced. However, they have the disadvantages that, because of the complexity of the process, there is a limitation on the size and shape of the object to be plated, and the resultant deposits are softer and less wear resistant than those deposited from aqueous solutions.<sup>89</sup>

Metallurgically bonded platinized anodes have also been produced. These are achieved by wrapping a thin platinum sheet over a cylindrical billet of titanium, vacuum encapsulating within a copper can, which acts as a lubricant, and extruding it to the required shape.<sup>9</sup> When used in seawater systems, the resultant copper layer has the advantage that it prevents fouling of the anode prior to energizing. Low porosity, ductile platinum coatings can be produced, but only on rod or wire anode forms. A variant has been produced that consists of a titanium rod spirally wound with platinum wire spot welded to the surface of the rod.<sup>90</sup>

As indicated above, platinized titanium anodes have the disadvantage that the protective passive film on the titanium can break down and pit at high applied anodic voltages, leading ultimately to anode failure. The potential at which the breakdown of titanium occurs is dependent upon the solution composition. In seawater, the breakdown potential of titanium is often considered to be  $\sim 9.5$  V versus SHE,<sup>81</sup> while values as low as 6 V in 5.8% NaCl have been reported.<sup>91</sup> The value of the breakdown potential for titanium is dependent upon the  $\text{Cl}^-$  concentration and in high purity waters may be relatively high.<sup>92</sup> The presence of certain anions for example  $\text{SO}_4^{2-}$ , favors passivation. At sulfate, when chloride ratios are above 4:1, the breakdown voltage increases from  $\sim 8$  to 35 V.<sup>93</sup> The presence of bromides and iodides significantly reduce the pitting potential for titanium (down to as low as 2 V), while fluorides and sulfates will increase it to as much as

35 V.<sup>93</sup> Temperature also has a significant effect on the anodic breakdown voltage of titanium, with an increase in temperature decreasing the breakdown potential. A prudent maximum operating potential for platinized titanium in seawater is 8.0 V.

Platinized titanium anodes may be operated at current densities as high as  $5400 \text{ A m}^{-2}$  (<sup>94</sup>); however, at these current densities there is the possibility that the breakdown potential of titanium may be exceeded. The normal operating current density range in seawater is  $250\text{--}750 \text{ A m}^{-2}$  (<sup>79</sup>) while that in brackish waters is given as  $100\text{--}300 \text{ A m}^{-2}$  (<sup>95</sup>) with values within the range  $100\text{--}150 \text{ A m}^{-2}$  being favored.<sup>9</sup> The consumption rate for platinized titanium anodes in seawater over the current density range  $300\text{--}5000 \text{ A m}^{-2}$  has been found to be directly related to the charge passed, with values of  $1\text{--}2 \mu\text{g A}^{-1} \text{ h}^{-1}$  being generally used as the basis for system design. The consumption rate is also dependent upon solution composition, the rate increasing with decreasing chloride concentration and may reach a peak value of  $435 \text{ mg A}^{-1} \text{ year}^{-1}$  at a chloride concentration to be associated with the concurrent evolution of oxygen and chlorine, the rates of which are about equal in a neutral solution containing  $2.5 \text{ g dm}^{-3} \text{ NaCl}$ .<sup>81</sup> In brackish waters, the platinum consumption rate may be as high as  $20 \mu\text{g A}^{-1} \text{ h}^{-1}$ , more than ten times the rate in seawater and increases with increase in current density. Baboian<sup>96</sup> reports consumption rates of  $\sim 13 \text{ mg A}^{-1} \text{ year}^{-1}$  in seawater over the current density range  $11.8\text{--}185 \text{ A m}^{-2}$ , while those in  $350 \Omega \text{ cm}$  water (brackish river water) he reports as  $92.3 \text{ mg A}^{-1} \text{ year}^{-1}$  at  $11.8 \text{ A m}^{-2}$ , increasing to  $117.8 \text{ mg A}^{-1} \text{ year}^{-1}$  at  $185 \text{ A m}^{-2}$ . The effect of temperature on the consumption rate of platinized titanium anodes has not been found to be significant over the ranges normally encountered in CP installations.

Failures of platinized titanium anodes have been found to occur for reasons other than consumption of platinum or attack on the titanium substrate caused by voltages incompatible with a particular electrolyte. The following are examples:

- Attack on the substrate when covered in mud or marine growth, prior to energizing, has been found to be a possible cause of failure, because of a buildup of acidity (reduction in pH) once the current is applied.<sup>97,98</sup> Some commercial guarantees require that the exposure period during which anodes remain unenergized must exceed 8 weeks.<sup>99</sup> If anodes are to be installed in seawater for extended periods prior to energizing, they

should be coated with a copper antifouling paint or electrodeposit.<sup>81</sup> The copper coating will dissolve when the anode is energized and will not affect the anode's subsequent performance or operation.

- Attack on the substrate by contact with calcareous scale can also cause platinum loss to occur. Anodes located close to the cathode or operating at high current densities can lead to a rapid build up of calcareous deposit, the major constituents of which are  $\text{Mg(OH)}_2$  and  $\text{Ca(OH)}_2$ .<sup>100</sup> The alkaline conditions so generated can lead to rapid dissolution of the platinum. The calcareous deposit can be removed by washing with dilute nitric acid.
- The formation of deposits on platinized anodes can cause anode degradation.<sup>88,97</sup> Thus, dissolved impurities present in water, which are liable to oxidation to insoluble oxides, for example Mn, Fe, Pb, and Sn, can have a detrimental effect on anode life. In the case of  $\text{MnO}_2$  films, it has been observed that  $\text{MnO}_2$  may alter the relative proportions of  $\text{Cl}_2$  and  $\text{O}_2$  produced and thereby, increase the Pt dissolution rate.<sup>9</sup> The oxides may be incorporated into the  $\text{TiO}_2$  oxide film and decrease the breakdown potential<sup>97</sup> or form thick deposits. The latter may limit electrolyte access and lead to the development of localized acidity, at concentrations sufficient to attack the underlying substrate.<sup>9</sup>
- The superimposition of AC ripple on the DC output from a transformer rectifier can, under certain circumstances, lead to increased platinum consumption rates and has been the subject of considerable research.<sup>97,101–103</sup> Indeed, when platinized titanium anodes were first used, it was recommended that the AC component was limited to 5% of the DC voltage.<sup>9</sup>
- The frequency of the superimposed AC voltage signal has also been shown to affect the consumption rate of platinum, which increases with decrease in frequency. At  $100\text{--}120 \text{ Hz}$  (the frequency of the AC component signal from a full-wave single-phase transformer rectifier) and above, the AC signal has a negligible effect on consumption rate, provided that the AC component did not allow the electrode to become negative. If negative potential 'spikes' do occur in the output wave form, even at  $100 \text{ Hz}$ , a considerable increase in platinum dissolution can occur.<sup>104</sup> This could be the case with a thyristor-controlled transformer rectifier operating at a relatively low current

output. At low-frequency AC (2 Hz), an increase in platinum dissolution rate of two to three times has been reported, while negative current spikes of a few milliseconds duration at this frequency can cause dissolution rates of  $\sim 190 \text{ mg A}^{-1} \text{ year}^{-1}$ . It is, therefore, recommended that all spurious waveforms on the DC supply to platinized anodes be avoided.

- Organic impurities in the electrolyte have also been quoted as increasing the rate of platinum dissolution when the metal is used as an anode in electroplating.<sup>97</sup> Saccharose was observed to increase the anodic dissolution of platinum by a factor of ten in a 3% brine solution,<sup>105</sup> but did not affect the anodic breakdown voltage for titanium. Other organic compounds that may also have an effect are brightening agents for Ni plating solutions of the naphthalene trisulfonic acid type, detergents, or wetting agents.
- Fatigue failure of cantilever anodes in flowing electrolytes can occur as a result of vortex shedding.<sup>106</sup> However, with proper design and adequate safety factors, these failures can be avoided.<sup>97,107</sup>
- Attention must be paid to end effects, particularly on cantilever anodes, for example, on long anodes that extend away from the cathode surface. Under these circumstances, the anode surface close to the cathode may be operating at a considerably higher current density than the mean value, with the exact values dependent upon the system geometry. The life of the platinized anode in this region would then be reduced in inverse proportion to the current density.

In seawater and brackish waters, platinized–titanium installations have now been in use for 50 years for jetties, offshore installations, ships and submarines,<sup>9,107</sup> and for internal protection, particularly of cooling-water systems.<sup>108</sup> Anode forms include rod, tubular, mesh, and plate. For the protection of heat exchangers, an extruded wire of copper-cored titanium–platinum has shown a reduction in current requirement, together with improved longitudinal current spread, over cantilever anodes.<sup>109,110</sup> This ‘continuous’ or coaxial anode is usually fitted around the water box periphery a few centimeters away from the tube-plate.

Although not suitable for direct burial, platinized–titanium anodes may also be used in soils when surrounded by a carbonaceous backfill. Warne and Berkeley<sup>111</sup> have investigated the performance of platinized–titanium anodes in carbonaceous backfills

and concluded that the anodes may be successfully operated in this way at current densities of up to  $200 \text{ A m}^{-2}$ . This also supplements the findings of Lewis,<sup>112</sup> who states that platinized–titanium anodes may be used in carbonaceous backfill without breakdown of the titanium oxide film. In a properly constructed groundbed, there will be little ionic conduction at the platinum surface, the primary conduction to the carbon being electron transfer.

Under some circumstances, platinized titanium can be used in open-hole groundbeds extending below the water table. However, the water chemistry within a borehole can be complex and may, in certain circumstances, contain contaminants which favor breakdown of the anodic film on titanium. In addition, the pH of the solution in a confined space will tend to decrease, and this will result in an increase in the corrosion rate of the platinum.

#### 4.20.5.3 Platinized Niobium and Tantalum

Platinum electrodeposition onto tantalum had been carried out as early as 1913<sup>113</sup> and the use of platinized tantalum as an anode was suggested in 1922,<sup>114</sup> while platinum electrodeposition on to niobium was first successfully carried out in 1950.<sup>115</sup> These anodes are similar in principle to their titanium equivalent, differing only in the fact that they can tolerate much higher operating potentials and hence, they can operate at much higher current density. They are considerably more expensive than platinized titanium, especially when expressed in terms of price per unit volume.<sup>88</sup> As niobium is cheaper than tantalum, the use of the latter has become rare. The extra cost of Nb anodes may be offset in certain applications by their superior electrical conductivity and higher breakdown voltages. **Table 6** gives the comparative breakdown potentials of Ti, Nb, and Ta in various solutions under laboratory conditions.

**Table 6** Comparison of breakdown potential

<i>Solution</i>	<i>Ti</i>	<i>Nb</i>	<i>Ta</i>
Seawater	9	120	120
Sulfate/Carbonate	60	255	280
Phosphate/Borate	80	250	280
Drinking water	37.5	250	280
Bromides	2–3		

Data reproduced from corresponding article in 3rd Edition of Shreir’s Corrosion.

There have been instances reported in the literature where the breakdown potential for Nb and Ta in seawater has been found to be lower than the generally accepted value of 120 V, with reported values in extreme instances as low as 20–40 V.<sup>116,117</sup> This has been attributed to contamination of the niobium surface from machining operations, grit blasting, or traces of copper lubricant used in anode manufacture. These traces of impurities, by becoming incorporated in the oxide film, decrease its dielectric properties and, thus, account for the lower breakdown voltage. Careful control of surface contamination in the manufacture of platinized niobium is, therefore, essential to minimize the lowering of the breakdown potential of niobium.

Lower breakdown potentials, leading to unexpected premature failure, have also been observed on platinized niobium anodes which have become buried in seabed silt.

Platinized niobium anodes can be prepared by electrodepositing platinum onto grit-blasted niobium, metallurgical coprocessing (cladding) or by welding platinum or platinum/iridium wire to niobium rod.<sup>116</sup> They cannot be prepared by thermal deposition because niobium oxidizes at 350 °C and good adhesion cannot be obtained. Both materials may be welded under argon, utilizing butt or plasma welding techniques.

Platinized niobium and tantalum anodes have found use in applications where their high breakdown voltages and hence higher operational current densities can be utilized. These include ship and cooling system anodes, which may need to operate in estuarine waters and therefore, require higher driving voltages, offshore structures where high reliability in service is required, domestic water tanks,<sup>118</sup> and deep-well open-hole groundbeds.<sup>119</sup> Efrid<sup>104</sup> found the consumption rate of platinized niobium in seawater over the range 5000–10 000 A m<sup>-2</sup> to be similar to that of platinized titanium, that is, 1 µg A<sup>-1</sup> h<sup>-1</sup>. However, at a current density of 30 000 A m<sup>-2</sup>, he observed an increase in the platinum consumption rate to 2 µg A<sup>-1</sup> h<sup>-1</sup> and concluded that this was the limiting current density for operating these anodes. Warne and Berkeley<sup>111</sup> report that the maximum current density for these anodes in seawater is 2000 A m<sup>-2</sup>, with a working current density of 500–1000 A m<sup>-2</sup>. The operating current density selected should, however, be commensurate with the desired anode life, platinum coating thickness, and platinum consumption rate in a given environment.

In open-hole deep-well groundbeds, platinized niobium anodes have been successfully operated at

a current density of 215 A m<sup>-2</sup> (<sup>120</sup>) and in the range 100–267 A m<sup>-2</sup>.<sup>121</sup> Toncre and Hayfield<sup>95</sup> have conducted work on the operating parameters of platinized niobium anodes in brackish waters and simulated groundbed environments. For an open-hole groundbed, they concluded that operational current densities of 400 A m<sup>-2</sup> or higher were the most economical, as they led to a lower consumption rate in sulfate-containing groundwaters. The platinum consumption rate in a deep-well environment may well alter because of variations in the environmental conditions. On extruded platinized niobium anodes a consumption rate of 175 mg A<sup>-1</sup> year<sup>-1</sup> was considered for design purposes, while that for electroplated platinized niobium was taken as 87.6 mg A<sup>-1</sup> year<sup>-1</sup>. In a backfilled deep-well groundbed, dissolution rates comparable with those for an open-hole environment were reported, that is, 87.6 mg A<sup>-1</sup> year<sup>-1</sup> at 200 A m<sup>-2</sup>. At lower current densities, it seems likely that the electrochemical processes would be limited to oxidation reactions involving coke alone and no electrochemical loss would occur on platinized niobium. Indeed, Baboian<sup>122</sup> reports negligible Pt consumption rates in carbonaceous backfill at current densities from 11.8 to 29 A m<sup>-2</sup>, increasing to 11.9 mg A<sup>-1</sup> at 57.9 A m<sup>-2</sup> and 13.5 mg A<sup>-1</sup> year<sup>-1</sup> at 185 A m<sup>-2</sup>. The wear rates at 57.9 and 185 A m<sup>-2</sup> were comparable to those Baboian observed in seawater. The relative merits of platinized titanium and niobium in a deep-well environment, in comparison with those of other anode materials, have been discussed by Stephens.<sup>123</sup>

#### 4.20.5.4 Mixed Metal Oxide Coated Titanium

Mixed metal oxide (MMO) anodes, as their name suggests, consist of a layer of precious metal oxide intermixed with titanium or tantalum oxide, on a titanium substrate. They were originally developed, by Beer,<sup>124,125</sup> for the production of chlorine and chlorates,<sup>126,127</sup> where they were used as a more corrosion resistant replacement for graphite at the very high current densities (10 000 A m<sup>-2</sup>) and extreme environmental conditions experienced in those applications. They are sometimes alternatively referred to as dimensionally stable anodes (DSA).

They have now gained wide acceptance as impressed current anodes for CP and have been in use for this purpose since 1971. The anode consists of a thin film of metal oxides deposited onto a chemically etched titanium substrate by thermal

decomposition of a solution of metal salts, usually chlorides, in an organic solvent. The solution is applied by painting or spraying on to the titanium surface and then allowing the solvent to evaporate. The anode is heated in a controlled atmosphere to a temperature at which the metal salts decompose (between 350 and 600 °C)<sup>128</sup> and form the oxides. Multiple layers are applied and heated until the required deposit thickness, which is typically 2–12.5 µm, is obtained. Thicker deposits become brittle and poorly adherent,<sup>129</sup> although deposits up to 25-µm thick can be produced. Only titanium substrates can be coated in this way because at the temperatures required by the anode manufacturing process niobium oxidizes excessively.

MMO coatings are usually on the basis of the use of ruthenium or iridium oxides, in combination with titanium or tantalum oxides, although palladium has also been used for some applications and additions of tin oxide are also sometimes used. The composition of mixed metal oxide used is dependent on the environment in which the anode will operate and is adjusted to favor either oxygen or chlorine evolution by varying the relative proportions of iridium and ruthenium. For chlorine production, RuO<sub>2</sub>-rich coatings are preferred, while for oxygen evolution IrO<sub>2</sub>-rich coatings are utilised.<sup>130</sup> The former would be used in seawater, and the latter for buried or concrete CP application. The precise composition of the coating is generally considered proprietary information and is not divulged by the anode manufacturers.

MMO coated anodes have a significantly lower consumption rate than those using platinum metal. In seawater, with the anode evolving chlorine, the consumption rate is 0.5–1 mg A<sup>-1</sup> year<sup>-1</sup>, while in freshwaters and soils where oxygen evolution predominates the rate is 6 mg A<sup>-1</sup> year<sup>-1</sup>.<sup>(128)</sup> These are one fifth to one tenth of the platinized anode loss rate. The current densities normally used for design purposes are 600 A m<sup>-2</sup> for seawater, and 100 A m<sup>-2</sup> for fresh water, saline mud, and coke breeze backfill.<sup>131</sup> Higher current densities may be utilized in certain circumstances, but this reduces the anode life for a given coating thickness. MMO coatings are porous and, therefore, the limitations on operating voltage for platinized titanium anodes apply equally to MMO coated titanium electrodes. It has been reported that breakdown of mixed metal oxide anodes may occur at 50–60 V in low-chloride concentration water but at only 10 V in chloride-rich environments.<sup>128</sup>

MMO anodes, like platinized Ti, can be supplied in a number of different forms including rod, tube,

plate, and wire. Their application is similar to that for platinized anodes, except that, with a suitable MMO formulation, they can be directly buried without the use of carbonaceous backfill. LIDA<sup>®</sup> anodes, consisting of tubular anodes distributed on a length of cable which passes through the tubes, which are then swaged to connectors at their center points, have been developed specifically for use in groundbeds, both deep-well and horizontal.

Another specific development has been the use of MMO coated titanium mesh for the CP of reinforcing steel in concrete structures.<sup>132,133,134</sup> The anode mesh is made from commercially pure titanium sheet ~0.5–2-mm thick expanded to provide a very open, diamond-shaped, mesh. The mesh size selected is dictated by the required cathode current. The anode mesh is joined on site using spot welded connections to a titanium strip or by niobium crimps, while electrical connections to the DC power source are made at selected locations using suitably encapsulated or crimped connections. The mesh is fixed to the concrete using nonmetallic fixings. The MMO in this application is usually a combination of iridium and tantalum oxides. The material once installed is then covered with a concrete or mortar coating, the minimum thickness of cover above the anode mesh being 10 mm, while 15 mm is preferred. Alternative methods of application for concrete structures have included installation of anode strips in diamond cut slots and MMO coated titanium rods inserted in grouted holes. As well as being suitable for controlling reinforcement corrosion in existing structures by CP, all these anode variants can be installed in new structures to provide cathodic prevention, the advantage of the latter being that much lower current densities are required for ‘prevention’ rather than ‘protection.’

#### 4.20.6 Ceramic Anodes

An electrically conductive titanium oxide based ceramic material has been developed and is marketed under the trade name ‘Ebonex.’<sup>®135</sup> This material consists principally of Ti<sub>4</sub>O<sub>7</sub> but may also contain some higher oxides. It is black in color, has an electrical resistivity of less than  $2 \times 10^{-4} \Omega \text{m}$  and can be operated at current densities up to 100 A m<sup>-2</sup> in 10% NaCl; however, if coated with a precious metal, it can be operated at considerably higher current densities up to 400 A m<sup>-2</sup>.<sup>(136)</sup> Consumption rates, even in concentrated sulfuric acid, are negligible. It is both porous and brittle, although its mechanical strength

can be improved and porosity reduced by resin impregnation, preferably with inorganic fillers. It has a high over-potential for oxygen evolution, is not affected by current reversal, and has no restriction on operating voltage, and the makers claim that it has an excellent resistance to both acid and alkali. It is, however, difficult and expensive to produce, requiring heating of pure compacted titanium oxide powder in hydrogen at  $\sim 1350^\circ\text{C}$ .

To date, the material has been used as an electrode in electrowinning, electrochlorination, batteries, and electrostatic precipitators. In tubular form, it has been used as a discrete anode on concrete CP and prevention. One feature restricting its more widespread application is the difficulty of making good, consistent electrical connection having sufficient reliability.

#### **4.20.7 Applications of Impressed-Current Anodes**

As will be clear from the discussions above, the types of anodes available for use in impressed-current CP have become more advanced with time, starting with steel, which is fully consumed with use and proceeding with increasing resistance to anodic dissolution, through silicon containing cast iron, graphite (and carbonaceous backfill), lead based alloys (including bielectrodes), platinized titanium to mixed metal oxide coated titanium. The current use of these materials in a number of CP applications is briefly outlined in the following sections. The final choice will be on the basis of a combination of operational factors (design life, environment, consumption rate, and ease of installation) and cost.

##### **4.20.7.1 Offshore and Marine**

The majority of offshore installations are protected from corrosion by the use of sacrificial-anode CP. A number of impressed current systems have been installed, but they have a number of disadvantages, most notably a need for continuing control and maintenance, and a tendency to mechanical failure. Where impressed-current protection has been used, it has been with platinized titanium or platinized niobium. MMO anodes have, on occasion, been used to retrofit protection to structures where life extension has been needed.

Impressed-current systems are more often used with marine structures such as jetties, where the

possibility of automatic current control allows for the varying current demand because of tidal movements. Very early systems used scrap steel anodes. The use of lead–silver was common up to  $\sim 30$  years ago, when platinized titanium became widely available. Most modern systems utilize MMO coated titanium in rod, tube, or plate form.

Systems for the protection of ship's hulls and, recently, floating production units used to use lead–silver anodes, but most installations today take advantage of the very low consumption rate of MMO materials.

##### **4.20.7.2 Onshore**

Most CP for onshore installations is provided using anode groundbeds backfilled with a carbonaceous material. The primary conductor anode is now commonly MMO coated titanium, which offers advantages in weight and ease of installation. However, silicon–iron is still in extensive use, while graphite and magnetite anodes are also available for these applications.

Canistered anodes utilize silicon–iron, platinized titanium or MMO anodes in carbonaceous backfill within a galvanized steel canister. Where ground conditions allow the use of open-hole deep-well groundbeds, silicon–iron or MMO anodes are usually used although again graphite and magnetite are also sometimes employed. Platinized niobium may be used where very high groundbed current output is required.

Under the bases of large diameter above-ground tanks, MMO coated titanium wire can be used to ensure good current distribution to the entire base surface. Conductive polymer coated wire is occasionally used for this application.

##### **4.20.7.3 Internal**

The earliest systems for the protection of the water boxes of seawater cooled condensers used steel or cast-iron anodes. The tendency now is to use platinized or MMO anodes, with occasional use of magnetite.

##### **4.20.7.4 Concrete**

Reinforced concrete structures that are fully immersed or buried in a corrosive environment may generally be protected using conventional cathodic protection groundbed design. However, for the CP of above-ground reinforced concrete structures,

for example, bridge decks, jetties, tunnel parking garages, and concrete buildings, a number of specific anode systems have been developed.

Some of the earliest systems were for bridge decks and used conductive asphalts. Where the additional weight and thickness can be accommodated, modern systems use an MMO coated mesh attached to the surface and covered with a layer of sprayed concrete or mortar. If weight is an issue or the additional thickness of mortar cannot be accepted, conductive coating can be used, or, alternatively strip or rod anodes can be incorporated in the concrete by slot cutting or drilling, respectively. Titanium oxide ceramic has sometimes been used as an alternative to MMO coated rods.

## Glossary

**Dolphin** A harbor structure that extends above the water level and is not connected to shore; they are installed when it would be impractical to extend the shoreline (e.g., with a pier or wharf) to provide a dry access facility.

## Abbreviations

**AC** Alternating current

**DC** Direct current

**emf** Electromotive force (V)

**$IR$**  Voltage (ohmic) drop due to current flow ( $I$ ) through a resistance ( $R$ )

**ln** Natural logarithm

**MMO** Mixed metal oxide

**PV** Photovoltaic

## Symbols

**$I$**  Current

**$M$**  Generic symbol for a metal

**$R$**  Resistance

**$V$**  Voltage

**$z$**  Number of electrons transferred in electrochemical reaction

**$\rho$**  Resistivity

## 4.21.1 Background and Introduction

The forms of corrosion that can be controlled by cathodic protection include all forms of general corrosion, pitting corrosion, graphitic corrosion, crevice corrosion, stress corrosion cracking, corrosion fatigue, cavitation corrosion, bacterial corrosion, etc. Cathodic protection can be applied to a wide range of metals and bimetallic couples of metals. Most applications are to steel, as this is the most common construction material, but cathodic protection, with revised protection criteria or limits, can be applied to stainless steels, copper, cupro nickel alloys, lead, aluminum alloys, and galvanized steel.

### 4.21.1.1 Structures that Are Cathodically Protected

There are many structures and installations that, in given circumstances, can benefit from the application of a cathodic protection system. For example, these include buried and submerged crude oil, fuel oil and gas tanks, and pipelines; offshore fixed oil and gas drilling and production platforms, buried and immersed water, fire protection, gas, and compressed air distribution schemes; metallic sewers and culverts; buried and immersed communication and power cables; deep-well casings for oil, gas, and water extraction; other buried tanks and the bases of tanks in contact with the ground; electrical transmission tower, aerial and wind-farm tower footings, sheet

steel piling, tubular and 'H'-piling associated with port and harbor facilities, and other infrastructure projects; immersed and buried steel tube tunnels; piers, wharfs, and other mooring facilities; cooling water systems including internals and externals of pipelines, intake screens, condenser water boxes pumps, etc.; gates, locks, and screens in irrigation and navigation canals; buried domestic oil distribution lines or buried pipelines for district central heating systems.

- Cathodic protection of internal surfaces is applied, in addition to the cooling water systems listed above, to surface and elevated water storage tanks (both potable and seawater, the latter often for firefighting purposes); condensers and heat exchangers; hot-water storage tanks, processing tanks, and vessels; hot and cold water domestic storage tanks; and process vessels in breweries and dairies (pasteurizers).
- Cathodic protection of floating structures is applied to the external hulls of most commercial and military vessels including vessels that are 'laid up' or 'in mothballs'; to the ballast compartments of tankers; floating oil and gas drilling and production facilities; floating dry-docks; barges (interior and exterior); dredgers; caisson gates; steel mooring pontoons; and navigation aids, for example, buoys.
- Cathodic protection of steel in concrete is applied to buried and immersed steel, reinforced and pre-stressed concrete pipelines, generally for water distribution; steel reinforced concrete foundations, piles and caissons of buildings, and port and harbor facilities; steel-reinforced concrete offshore oil and gas drilling, production, and storage facilities; steel-reinforced atmospherically exposed highway structures (bridges, elevated road support structures, etc.) and bridge decks; buried and immersed tunnels; buried reinforcement concrete basements and car parks; multistory car parks; and buildings.

In many countries, the safety and environmental advantages of cathodic protection are sufficiently well acknowledged that there is legislation requiring effective cathodic protection of buried or immersed pipelines carrying products such as crude oil, refined product, and gas, and there are Insurance and Classification Society requirements for effective cathodic protection of offshore oils and gas drilling and production facilities and for ships.

#### 4.21.1.2 Type of System

The use of an impressed-current system or galvanic anodes will provide satisfactory cathodic protection,

but each has advantages and disadvantages with respect to the other (Table 1).

##### 4.21.1.2.1 Reactions at anodes

Galvanic anodes and impressed-current anodes are discussed elsewhere, but further comment is relevant here in relation to the choice of a particular system for a specific environment. In this connection, it should be noted that the conductivity of the environment and the nature of the anode reactions are of fundamental importance. The main anodic reactions are electrochemical oxidation processes and may be summarized as follows:

##### For galvanic anodes:

Primary reaction:  $M \Rightarrow M^{z+} + ze^-$  (i.e., metal dissolution)

Secondary reaction:  $M^{z+} + zH_2O \Rightarrow M(OH)_z + zH^+$  (i.e., precipitation of metal hydroxide)

where  $M$  represents the anode material and  $z$  the number of electrons transferred in the reaction (i.e., the electrochemical equivalent). For zinc and magnesium,  $z = 2$  and for aluminum,  $z = 3$ .

##### For impressed-current anodes:

$3H_2O \Rightarrow 2H_2O^+ + 2e^- + \frac{1}{2}O_2$  (i.e., oxidation of water/evolution of oxygen) and/or

$2Cl^- \Rightarrow Cl_2 + 2e^-$  (i.e., evolution of chlorine)

or, in the case of graphite or graphite-filled polymer anodes

$C + O_2 \Rightarrow CO_2$  (i.e., oxidation of carbon to carbon dioxide)

It should be noted that when metals such as zinc and aluminum are used as galvanic anodes, the anode reaction will be predominantly as above although self corrosion may also occur to a greater or lesser extent. The emf between magnesium, the most active (negative) galvanic anode, and iron is  $\sim 0.7$  V, the emf of power-impressed systems can range from 6 V to typically a maximum of 48 V (limited for personnel safety reasons), depending on the power source employed. Thus, galvanic anodes are normally restricted to environments having a relatively lower resistivity (e.g.,  $< 50 \Omega m$ ), whereas there is no similar limitation in the use of impressed-current systems.

In the case of galvanic anodes, the electrons that are required to depress the potential of the structure to be protected are supplied by the primary reaction above and, providing the metal ions can diffuse away from the structure before they react with water to form insoluble hydroxides, the reaction will be unimpeded and will take place at a low overpotential. If, however, the metal hydroxide precipitates on the

**Table 1** Comparison of galvanic anode and impressed current cathodic protection systems

<i>Method</i>	<i>Galvanic (sacrificial) anode cathodic protection</i>	<i>Impressed-current cathodic protection</i>
Characteristics	Protection by current from galvanic/sacrificial consumption of more electronegative metal anodes	Protection by current from DC power supply; typically a transformer rectifier passed through more inert anodes
Anode materials	Magnesium, aluminum, and zinc alloys. Occasionally iron for protection of copper and copper alloys	Mixed metal oxide (Pt, Ir, Ru)-coated titanium; platinum-plated titanium and niobium; cast silicon-iron and silicon with chrome; conductive ceramic (monolithic $Ti_4O_7$ ). Historically carbon; lead alloy, and lead alloy with Pt microelectrodes; scrap iron; conductive polymers
Power	Independent of power source Well established $Ah\ kg^{-1}$ capacity figures for proven alloys Cannot be connected incorrectly with polarity reversed.	Requires electrical power supply Can be connected incorrectly with polarity reversed and cause accelerated corrosion. (There are polarity reversal protection circuits available)
Installation	Simple, but may require significant welding of anode steel cores to structure	Complex; requires significant cable routing between the power source, the anodes, and the cathode
Reliability	High, if properly designed and installed Entire cathodic protection system directly connected to the structure; only the galvanic (sacrificial) anode material is consumed by corrosion	High, if properly designed, installed, and maintained Historically many offshore and port and harbor impressed-current systems have failed due to mechanically inadequate designs. Many marine systems have failed due to poor maintenance or simply being switched off The entire anode (+ve) circuit is at risk of forced corrosion if cables or anode/cable connections are improperly designed or are damaged. Positive cable damage and poor anode/cable design are significant risks to impressed current system performance
Design complexity	Simple, but requires competent anode and steel core design for anode current delivery through life and for certain applications may require rigorous structural assessment of welded connections between steel core and structure	Complex. Designs frequently ignore key elements of competent design such as optimum anode-cathode spacing calculations for optimum current distribution. Mechanical integrity of anodes, anode/cable connections, cable management systems, and monitoring systems often inadequate
Typical design life	5–50 years High cost and weight for long-life systems	10–100 years but electrical/electronic systems likely to require 100% replacement at c. 25 years
Interaction or stray current	Due to normally low individual anode current outputs and large numbers of anodes, interaction effects to third-party structures are often negligible High-current anode arrays can cause the same interaction effects as impressed-current systems of same current output Interaction testing necessary in sensitive locations and with high-current designs	Very likely  Interaction testing with third parties should be mandatory. Remedial action may be simple and low cost
Advantages	Simple. Reliable  'Self-control' current output to meet demand within a limited range if properly designed	Ability to easily increase or decrease current to meet changing demands or errors in design assessment Ability to remote-control and monitor via electronic devices Ability to measure 'instant OFF' potentials with minimum IR drop errors Ability to operate in high electrical resistivity electrolytes and provide high currents from relatively small installations

**Table 1** Continued

<i>Method</i>	<i>Galvanic (sacrificial) anode cathodic protection</i>	<i>Impressed-current cathodic protection</i>
Limitations	<p>Electrical resistivity of electrolyte</p> <p>Typically <math>&lt;10\ \Omega\text{ m}</math> in saline water for aluminum anodes</p> <p>Typically <math>&lt;20\ \Omega\text{ m}</math> in saline water and soils for zinc anodes (although Zn ribbon can be used effectively to say <math>50\ \Omega\text{ m}</math>)</p> <p>Typically <math>&lt;50\ \Omega\text{ m}</math> in waters and soils for Mg anodes (although 'high voltage' and ribbon anodes can extend this)</p> <p>Typically, large numbers of anodes of considerable size are required for large current cathodic protection systems</p> <p>All anodes may not consume at the same rate if local current demands or resistivities vary</p> <p>Monitoring and control of galvanic anodes, although possible, is often limited</p>	<p>May be uneconomical for small schemes due to high unit cost of electrical power supply and transformer rectifier or control system</p> <p>Can use photovoltaic and/wind generators for relatively small schemes</p> <p>All elements of the anodic (+ve) circuit must be electrically isolated from the structure. Thus risks of failure by short circuits (particularly relevant to reinforced concrete applications where anode/cathode spacings may be as low as 15 mm). Thus, hull penetrations are needed for ship and floating structure applications</p>
Prime applications	<p>Offshore oil and gas facilities due to high reliability</p> <p>Port and harbor piled installations; high reliability, low inspection/maintenance requirement and low interaction risk</p> <p>Lock gates, tidal and flood protection facilities</p> <p>Small onshore applications; short pipelines</p> <p>Domestic water tanks</p> <p>Ships' internal tanks</p> <p>Offshore wind farm facilities</p>	<p>Offshore oil and gas facilities with weight limitations; very rigorous design process following multimillion £/\$ failures</p> <p>Port and harbor applications wherein capital cost assessment has outweighed the risks. Some failures</p> <p>Large/long pipeline applications. High reliability due to established design practice and relatively benign environment</p> <p>Large buried tanks and tank bottoms of 'on grade' tanks</p> <p>Cooling water applications where small anodes are essential</p> <p>Reinforced concrete applications wherein the high resistivity of the concrete often dictates impressed current</p> <p>Ship's hulls where the small size and low hydrodynamic profile is important</p>
Inspection and maintenance	Limited simple testing to confirm performance and to monitor consumption of anodes. Typically annual. If design-adequate, maintenance limited to replacement of depleted/consumed anodes at end of design life	Significant regular inspection requirements. Typically monthly for function check and three-monthly for performance verification. Maintenance typically required to power supplies, anodes, and monitoring systems
Stray current or drainage bonds (DC)	–	Effectively impressed current systems deriving their current from DC traction or similar stray current DC source. Can be directly bonded, controlled to a limited extent with resistive and rectifier networks or supplemented with an additional DC power source
Stray current dissipation (DC and AC)	<p>Effectively galvanic anode systems which might be used alone or to supplement an impressed-current system and used to provide a safe, low electrical resistance, connection to earth (soil or water typically) to allow DC or AC current to pass from the structure to earth without causing DC or AC corrosion to the structure</p> <p>Increasingly important on pipelines with very high electrical resistance coatings in the vicinity of AC electrical distribution networks</p>	–

surface of the metal as a nonconducting passive film, the anode reaction will be stifled and this situation must be avoided if the anode is to operate satisfactorily. Much development work has been expended in developing galvanic anode alloys which are reliable in known electrolytes and which do not suffer from stifling by anode reaction products.

In the case of nonreactive impressed-current anodes, rapid transport of the reactants ( $\text{H}_2\text{O}$  and  $\text{Cl}^-$ ) to and the reaction products ( $\text{O}_2$  and  $\text{Cl}_2$ ) away from the anode surface is essential if the anode reaction is to proceed at low overpotentials. This presents no problems in seawater, and for this reason the surface areas of the anodes are comparatively small and the anode current densities correspondingly high. Thus, in seawater, inert anodes such as mixed metal oxide-coated titanium (MMO/Ti) and platinized titanium can operate at up to  $1000 \text{ A m}^{-2}$ , since the anode reaction occurs with little overpotential, and there is rapid transport of  $\text{Cl}^-$  to and  $\text{Cl}_2$  away from the anode surface. In this connection, it should be noted that even in a water of high chlorinity such as seawater, oxygen evolution should occur in preference to chlorine evolution on thermodynamic grounds. This follows from the fact that the equilibrium potential of the oxygen evolution reaction in neutral solutions is  $0.84 \text{ V}$ , whereas the corresponding value for the chlorine evolution is  $1.34 \text{ V}$ , that is,  $0.5 \text{ V}$  higher. However, the chlorine evolution reaction occurs with only a small overpotential, whereas very appreciable overpotentials are required for oxygen evolution, and this latter reaction will occur therefore only at high current densities. Even in waters of low salinity, chlorine evolution will therefore tend to occur in preference to oxygen evolution at low overpotentials.

In the case of MMO/Ti, the consumption rate of the coating will be at its lowest ( $\sim 0.2 \mu\text{g}(\text{Ah})^{-1}$ ) when operated in open seawater, will increase in brackish water where a greater proportion of oxygen is evolved (to  $\sim 0.45 \mu\text{g}(\text{Ah})^{-1}$ ), and will be maximum in saline mud ( $\sim 1\text{--}1.5 \mu\text{g}(\text{Ah})^{-1}$ ).

In the protection of pipelines or other underground structures with buried anodes (often in 'groundbeds' or arrays of buried anodes), the anode reaction is dependent on diffusion of water to the anode surface and oxygen and  $\text{CO}_2$  away from it. Since these processes do not occur with the same mobility as in water, it is necessary to use a very large surface area of anode and a corresponding low current density. For this reason and to further reduce the electrical resistance of the anode to earth, the actual anode is a carbonaceous backfill of considerably greater dimensions than the anodes laid within the backfill. Silicon-iron or

MMO/Ti anodes are used primarily to make electrical contact between the cable and the backfill. It can also be seen from the oxygen evolution reaction above that the products of the oxidation of water are oxygen and hydrated hydrogen ions, which will migrate away from the anode surface under the influence of the field, thus removing two of the three water molecules that participate in the reaction, and this will tend to dehydrate the groundbed. In addition, the electric field between the anode and the cathode will cause electro-osmosis, which will further dehydrate the groundbed. These difficulties can be overcome, when feasible, by locating the groundbed below the water table.

#### **4.21.1.2.2 Galvanic anode systems**

*Advantages:* No external source of power is required; installation is relatively simple; the danger of cathodic protection interaction is minimized; it is more economical for small schemes; the danger of over protection is normally alleviated; uniform current distribution can be easily achieved by using small anode currents from many anodes; maintenance is not required apart from routine potential checks and replacement of anodes at the end of their useful life; it involves no running costs.

*Disadvantages:* Maximum anode output is delivered when first installed; this decreases with decreasing anode size with time when additional current may be required to overcome coating deterioration; current output in high-resistivity electrolytes might be too low and render anodes ineffective; large numbers of anodes may be required to protect large structures resulting in high anode installation and replacement costs; anodes may require replacement at frequent intervals when current output is high and/or maximum size is limited.

#### **4.21.1.2.3 Impressed-current systems**

*Advantages:* One installation can protect a large area of metal; systems can be designed with a reserve voltage and amperage to cater for increasing current requirement due to coating deterioration; current output can be easily varied to suit requirements; schemes can be designed for a life in excess of 25 years; current requirements can be readily monitored on the transformer-rectifier or other DC source; automatic control of current output or of the structure potential can be achieved.

*Disadvantages:* Possible interaction/stray current effects on other buried structures; their use is subject to the availability of a suitable AC supply source or other source of DC; regular electrical maintenance checks and inspection are required; running cost for

**Figure 1** Bond between pipeline and DC substation.

electrical supply is usually not very high except in the case of bare marine structures and in power stations wherein structures are often bare and include bimetallic couples; it is subject to power shutdowns and failures.

#### 4.21.1.2.4 Hybrid systems

Offshore structures are sometimes protected by hybrid systems using both galvanic and impressed-current anodes. These have the advantage that protection of the steel by the galvanic anodes will be effective as soon as the platform enters the sea, which is particularly advantageous since some time may elapse before the power generators required for the impressed-current system are operating.

#### 4.21.1.2.5 Stray-current bonding or forced drainage

Stray-current schemes are once again increasing in occurrence in the United Kingdom, as more localities have widespread DC transport systems arising from new tram- or light rail-based mass transport systems in the major conurbations. Such systems are extensively used in overseas countries where DC transport systems are in widespread use, that is, most of mainland Europe, Australia, and South Africa, with large schemes having been introduced into North America.

Where stray-current bonding can be employed, it is normally the most economical method of applying cathodic protection since the power required is supplied gratis by the transport system.

In such systems, it is necessary to provide a metallic bond between the pipeline and the negative bus of the railway substation. By providing such a bond, the equivalent of a cathodic protection system is established whereby the current discharged from the traction-system rails is picked up by all portions of the pipeline and drained off via the bond. The bond must have

sufficient carrying capacity to handle the maximum current drained without damage. In order to ensure that the direction of current flow in the bond does not reverse, it is normal to employ a reverse-current prevention device or 'electrolysis switch.' This may take the form of a relay-actuated contactor which opens automatically when the current reverses. Diodes are now more commonly used as blocking valves to accomplish the same purpose. They are wired into the circuit so as to ensure that the current can flow to the negative bus bar system only. Sufficiently rated diodes must be used in parallel to handle the maximum amount of current anticipated. Also, the inverse voltage rating (peak inverse voltage; PIV) of the diodes must be sufficient to resist the maximum reverse voltage between the negative bus bar and the pipeline (Figure 1).

Obviously the cathodic protection provided to the structure as a result of this system will be partial; it will not be provided when the traction system is not operational (many systems do not operate at night) or when the distribution of the traction units and substations is such that the current in the controlled bond is in the wrong direction and is blocked by the diodes or contactor. Some systems will include, separately or in the same installations, a potential-controlled transformer-rectifier, which will supplement the current from the traction bond and provide more continuous and better controlled cathodic protection.

### 4.21.2 Design of a Cathodic Protection System

#### 4.21.2.1 Initial Design Process

The design of a cathodic protection scheme should follow the general process outlined below. (see also Table 2). The design of any cathodic protection

**Table 2** Summary of the cathodic protection design process**Common to both galvanic and impressed-current systems**

Determine electrolyte resistivity and corrosivity  
 Determine other factors that will affect corrosion rate and current density: Soil type, temperature, flow rate (in waters), chloride level in concrete, bacterial activity  
 Assess materials of construction and their impact on corrosion performance and cathodic protection current density and safe metal/electrolyte potential limits  
 Determine/agree structure design life with client and determine the optimum design life (and replacement strategy if required) for the cathodic protection system  
 Determine if cathodic protection is necessary to deliver design life of structure in the assessed environment with appropriate factors of safety  
 Determine appropriate metal/electrolyte protection potential (criteria) noting that bacterial activity will likely require a more negative metal/electrolyte protection criteria and that many metals and coatings will have a safe negative potential limit beyond which the metals may suffer hydrogen embrittlement (high-strength steels and cupronickel alloys) or corrosion (amphoteric metals such as aluminum) or the coatings may suffer disbondment  
 Determine coating quality (if any) and estimate initial, mean, and final coating breakdown %  
 Calculate metal surface area in the electrolyte; subdivide if conditions affecting current demand vary within structure/electrolyte  
 Determine/estimate initial, mean, and final current density figures taking account of the electrolyte/environment and coating performance as above. Where possible, consider past performance in same/similar electrolytes/environments/locations  
 Calculate initial, mean, and final current demand  
 Determine electrical continuity of structure and any requirements to establish necessary continuity  
 Consider necessity of electrical isolation of structure from other structures/elements in order to restrict cathodic protection current flow to other structures/elements OR estimate this current flow and make allowance for it.  
 Consider proximity of other structures/services and the impact of the new cathodic protection system on them (DC interference/stray current from the cathodic protection system to third-party structures). Make allowances for minimizing these impacts, testing, and remedial actions  
 Consider proximity of other structures/services and their impact on the new cathodic protection system (DC and AC interference/stray current to the structure receiving the new cathodic protection system from third-party structures). Make allowances for minimizing these impacts, testing, and remedial actions  
 Determine optimum cathodic protection solution: galvanic anode or impressed current, on basis of performance, cost, reliability, suitability to established client operational and maintenance capabilities, electrical power supply availability, and other relevant factors  
 Determine optimum performance monitoring provisions and procedures  
 Document all of the above

**Galvanic anode systems**

Select optimum anode alloy for electrolyte and service (temperature, safety, potability)  
 Determine realistic anode performance characteristics (capacity ( $\text{Ah kg}^{-1}$ ) and closed-circuit operating potential) from the literature, and independent test data  
 Calculate mass of alloy from capacity, mean current demand, design life, and utilization factor (the percentage of the total mass that can be utilized effectively in protection, typically 80–90% subject to steel core design, the remaining 10–20% of material may be too small to deliver end of life current or may be dislodged from the core). The core design is important in delivering high utilization factors  
 Select/design anode shape to deliver calculated mass and current output at all of initial, mean, and final conditions taking proper account of the reducing size of the anode and the impact of core design on end of life dimensions

**Impressed-current systems**

Select optimum anode type for electrolyte and service  
 Determine realistic anode performance characteristics (capacity ( $\text{Ah kg}^{-1}$  for silicon-iron and similar or wear rate for MMO/Ti, Pt/Ti and Pt/Nb)) and maximum safe operating voltage) from the literature, and independent test data  
 Determine optimum distribution of anodes and (if appropriate) the use of carbonaceous backfill to reduce resistance and increase anode life. Ensure anode/cable design and cable insulation/sheath materials are suitable for use in acidic, nascent chlorine, and oxygen-evolving environments so that the full capacity of the anode can be delivered  
 Design anode shape/size (with groundbed backfill as appropriate) to deliver suitable anode/electrolyte resistance using classical electrode/earth resistance formulae. Allow for back emf (the potential between anode/electrolyte/cathode) and cable resistance in determining the required driving voltage from the DC power supply

Continued

Table 2 Continued

<i>Galvanic anode systems</i>	<i>Impressed-current systems</i>
<p>This should be undertaken using the classical electrode/earth resistance formulae to determine anode/electrolyte resistance and the Ohms Law to calculate current output (using the driving voltage as the closed-circuit operating potential of the anode less the protection criteria potential selected earlier). For cable-connected galvanic anodes, include the cable resistance in these calculations</p> <p>Determine optimum anode–cathode and anode–anode spacings and then determine whether the calculated anode current outputs should be reduced because of anode/cathode or anode/anode mutual interference (anode and cathode tension hill) and that the attenuation of protection between anodes will deliver adequate protection at mid points</p> <p>Confirm that the steel core design of the anode is structurally sufficient for the application</p> <p>–</p> <p>–</p>	<p>Determine optimum anode/cathode spacing to deliver uniform current distribution, to minimize interaction to third-party structures</p> <p>For buried applications, the locations should take account of the availability of electrical power supplies, the location of lower resistivity and wet soil conditions, and the avoidance of mechanical damage or future developments</p> <p>Calculate optimum anode–cathode spacing using the anode tension hill formulae. Simplistically: <math>V = \frac{I\rho}{2\pi r}</math> where <math>V</math> is the local voltage shift in the electrolyte due to the voltage cone around the anode <math>r</math> meters from the anode and <math>\rho</math> is the soil resistivity in <math>\Omega</math> m</p> <p>The spacing might be determined by interaction issues with a nearby third-party structure or by attenuation/distribution along a pipeline. The local voltage cone value will not affect pipe/soil potential remote from the anode, so the voltage cone value may need to be limited to, say, 0.5 V to avoid excessive pipe/soil potential at the nearest point to the groundbed</p> <p>Determine (by classical attenuation formulae on pipelines, sometimes by mathematical modeling for more complex applications) the attenuation between the impressed current installation locations and the remote ends or mid-points between additional installations</p> <p>Determine the optimum control for the impressed current system based on changes in electrolyte (e.g., sea/freshwater in estuaries or dry/wet ground conditions for buried applications, or flow/no flow in cooling water systems), in service (ships trading in different oceans, salinity, and temperature) or in structure/electrolyte immersion (tides):</p> <ul style="list-style-type: none"> <li>• Manual constant voltage (simple), optimum if all conditions stable</li> <li>• Manual constant current (simple closed loop) optimum if cathode current demand is stable but anode/electrolyte resistance changes</li> <li>• Potential control (more complex, relies on performance of steel/electrolyte potential measurement provisions of test connections and permanent reference electrodes being reliable) optimum if cathode current demand changes and will also accommodate anode/electrolyte resistance changes</li> </ul> <p>Determine whether remote monitoring and/or remote control (typically via telephone or GSM modem) will deliver either or both greater security of performance and lower costs of performance verification and maintenance</p>
<p><i>Common to both galvanic and impressed-current systems</i></p> <p>Where necessary these calculations may be iterative until a fully compliant solution is determined</p> <p>Determine optimum performance verification monitoring and inspection procedures and facilities</p> <p>Determine optimum inspection and testing requirements during installation and optimum precommissioning and commissioning procedures along with future operation and maintenance procedures</p> <p>Undertake a design risk assessment to assess, document, and, wherever possible, minimize the risks involved in the implementation of the design</p> <p>Document all of the above</p>	

scheme should be carried out by specialists who are suitably trained, experienced, and accredited as competent in the specific field of application.

Good practice in modern underground or underwater pipeline structures involves the use of good coatings in combination with cathodic protection. With a well coated structure, the cathodic protection system only protects the minute areas of steel exposed to the corrosive environment rather than the whole surface of an uncoated structure. The effect of coatings can be demonstrated by comparing the current density of a bare steel pipeline in average soil conditions, which could be up to  $30 \text{ mA m}^{-2}$ , with that achieved on a well coated and inspected line where a current density of only  $0.01 \text{ mA m}^{-2}$  or even lower may be required to obtain satisfactory cathodic protection. In all cases, the current density for protection is based on the superficial area of the whole structure.

Caution should be exercised when considering the suitability of coatings for the long-term protection of structures either without or in conjunction with cathodic protection. It is important that the long-term adhesion of the coatings to the surface is secure and that the electrical properties of the coatings over the full life and their impact on matters such as ac corrosion, stray current, and monitoring are properly assessed. It may be that the superficially 'best performing' coating for, say, a pipeline may present long-term disbondment and corrosion risk below the outer sheath and/or high risk of significant AC or DC stray current effects plus difficult-to-interpret/irrelevant cathodic protection monitoring data due to the particular dielectric properties of the coatings.

Many offshore structures and piled port and harbor structures are of bare steel based on the economics that the application of a high-quality coating can actually cost more than the application of a simple cathodic protection system to these bare structures.

Cathodic protection to steel in concrete is almost always to bare steel in concrete; the performance of coated reinforcement in concrete has not delivered its early promise in preventing corrosion in chloride-contaminated concrete, and the application of cathodic protection to coated reinforcement is complicated by electrical continuity issues and may be less than optimally effective due to long-term disbondment of coatings.

#### 4.21.2.2 Surface Area

In the case of underground pipelines, calculation of the superficial surface area can be obtained from the

diameter and length of the line involved. The superficial surface area should include any off-takes and other metal structures in electrical contact with the main line.

For marine structures, the area should include all submerged steel work below the high-tide level for impressed-current systems, but for galvanic systems, surface areas at both the high-tide and mid-tide levels may be required for parallel calculations of peak current demand for anode shape calculations and mean current demand for anode weight calculations. The surface areas may need to be split into different levels, as the current density requirements will vary with flow rate, oxygen content, and temperature, all of which vary with depth. Particular attention may need to be given in the cathodic protection design to areas of geometric complexity such as riser frames and pile guides; these may need local anode provisions to ensure that there is sufficient current distribution into these complex areas.

In the case of plants such as power stations, details of the water boxes, number of passes on coolers, and detailed assessment drawings are required in order to determine the local current density requirements in what may be bimetallic couples and high flow rate locations of the systems. Some parts of the structures may be bare and others coated.

In the case of ships, details of the full underwater submerged area at full load are needed along with details of sea chests, thrusters, and other features of the vessel design that will affect the cathodic protection design, including whether the vessel is intended for ice service (which will affect both the anode design and the coating breakdown allowances).

For steel-reinforced concrete, the steel surface area and its local disposition (steel density) require to be calculated on a very local basis (typically in local areas of  $\sim 1 \text{ m}^2$ ) because most anode systems will be installed in the concrete only some 15–100 mm away from the reinforcement and current distribution will therefore be limited. It is therefore essential, for uniform protection levels and uniform anode consumption rates, that the local anode provision properly reflects the local steel current demand; thus the steel surface areas need to be calculated and presented in considerable detail.

#### 4.21.2.3 Electrical Continuity

It is essential for any structure to be fully electrically continuous. In the case of pipelines, welded joints are obviously no problem, but mechanical joints require bonding. For marine structures, individual piles

and fendering must be electrically connected by welding either via the reinforcing bars in the concrete deck slab or separately. In power stations and ships, rotating shafts must be bonded into the structure by means of brush gear or a suitable alternative. In the case of offshore mooring installations, it may be considered to install a bonding cable to bring dolphins, etc. into an impressed current system but it is more normal to protect isolated elements, such as dolphins without walkways, with their own galvanic anode systems even if the main cathodic protection system is impressed current.

For steel-reinforced concrete structures, normal steel-fixing good practice is generally adequate to present a steel matrix that is sufficiently electrically continuous to allow all individual bars to receive full cathodic protection. In cathodic protection to new reinforced concrete structures, electrical continuity testing will be undertaken during steel fixing, and limited provisions of welded continuity bars may be required to ensure that all bars are electrically continuous (it is normally taken that  $1\ \Omega$  bar-to-bar resistance can be accepted as adequate within a matrix). In cathodic protection of existing reinforced concrete structures wherein corrosion has initiated, it is normal to test all bars exposed in concrete repair areas (at which the steel ties are likely to have corroded and corrosion products may have forced bars apart) and to undertake representative additional testing, following an assessment of the structure and its drawings, to prove the quality of general continuity within the reinforcement matrix. It is sometimes necessary to cut longitudinal and circumferential chases in the concrete to expose all bars and continuity-bond them.

#### 4.21.2.4 Estimate of Current Required

The surface area of the structure is calculated, and the current density required for the particular environment is selected (Table 3). In the case of an existing structure, the condition of the coating may be unknown and the application of a temporary cathodic protection system may be necessary to determine the amount of current required for protection, as established by the potential. Such a test to determine the absolute amount of current required is known as a current drain test. Misleading information may, however, be obtained if the results from current drainage tests on bare or coated steel in seawater are extrapolated, because long-term polarization effects, together with the formation of a calcareous deposit on the structure, may

considerably reduce eventual current requirements. On the other hand, in estuaries and polluted waters, special care must be taken to allow for seasonal and other variable factors that may require higher current densities.

#### 4.21.2.5 Establishing Electrolyte Resistivity

To enable a satisfactory cathodic protection scheme to be designed, it is necessary to determine the resistivity of the electrolyte (soil, water, or concrete). This information is necessary to enable the current output of anodes to be determined together with their position and power source voltage, and it also provides an indication of the aggressiveness of the environment; in general the lower the resistivity, the more aggressive the environment.

#### 4.21.2.6 Economics

After evaluating these variables, it must then be decided which type of system, that is, galvanic anode or impressed current, would be the most economical under the prevailing conditions. For instance, it would obviously be very expensive to install an impressed-current system on only 100 m of fire main. Similarly, it would be equally uneconomical to install a galvanic anode system on hundreds of miles of high-pressure, poorly coated gas main. Further, there is little benefit in providing a complex impressed-current system to an environment/location/client without resources to adequately monitor, adjust, and maintain the system. Therefore, each structure should be individually assessed taking note of all the factors involved in order to determine the optimum cathodic protection system (see Table 3).

#### 4.21.3 Impressed-Current Systems

Cathodic protection schemes utilizing the impressed-current method fall into two basic groups, dictated by the anode material:

*Group 1:* These anode materials have relatively high consumption rates, and their dimensions generally change during consumption. They comprise silicon-iron (and historically graphite and scrap steel) anodes used for buried structures and landward faces of sheet steel piled jetties, wharves, etc.; conductive coatings containing graphite used in cathodic protection of steel in concrete; conductive polymers containing graphite used

**Table 3** Typical current density figures for cathodic protection

<i>Environment</i>	<i>Estimated current density for cathodic protection based on superficial surface area mA m<sup>-2</sup></i>
<b>Bare steel</b>	
Sterile, neutral soils	4–16
Well aerated neutral soil	20–35
Dry well aerated soil	5–16
Wet soil, moderate/severely corrosive	25–65
Highly acidic soil	50–165
Soil supporting active sulfate-reducing bacteria	400–500
Fresh water, no flow	50–60
Fresh water flow	50–70
Turbulent fresh water containing dissolved oxygen	50–170
Fresh water at 70 °C	50–170
Polluted estuarine water	500–1600
<b>Seawater</b>	
Tropical >20 °C	Initial: 120–180; mean: 40–90; final: 80–130
Subtropical 12–20 °C	Initial: 140–200; mean: 50–100; final: 90–150
Temperate 7–11 °C	Initial: 170–220; mean: 60–110; final: 110–170
Arctic <7 °C	Initial: 200–250; mean: 80–120; final: 130–170
Chemicals, acids or alkaline solutions in process tanks	30–300
Heat exchanger water boxes with nonferrous tube plates and tubes and no coatings	500–1500
<b>Steel in concrete</b>	
Note: These current densities are to protect steel in non-water-saturated concrete to the appropriate protection criteria for steel in concrete. For buried steel connected to steel in concrete (such as at valve pits or pump stations where isolation has not been provided), the allowance for current drained to the steel in concrete in order to protect steel in soil to its appropriate protection criteria should be increased by a factor of 3–5. The figure 'prior to corrosion initiation' is adequate for fully immersed concrete	
These figures are ALL with reference to steel surface area; some US designs are incongruously based on concrete surface area and presumably assume a uniform steel density per unit area of concrete; such an assumption is incorrect	
Following corrosion initiation temperate	Initial: 10–20; mean/final: 2–15
Prior to corrosion initiation	0.2–2
<b>Coated steel pipelines &lt;30 °C assuming 30-year life</b>	
Coated with glass-reinforced coal tar or asphalt bitumen enamels, asphalt mastic, or butyl rubber tape assuming no massive failures	Initial: 0.040; mean 0.100; final 0.200
Fusion-bonded epoxy, liquid epoxy, coal tar epoxy assuming no massive failures	Initial: 0.010; mean 0.020; final 0.050
Three-layer polyethylene or polypropylene assuming no massive failure. Caution: failure can result in disbondment and shielding. Electrical characteristics can be so 'good' that the pipelines become vulnerable to AC and DC interaction and very difficult to monitor real pipe/soil potentials	Initial: 0.002; mean 0.005; final 0.010

Note: All of the above are general guidance figures only. Wherever possible, a design should be based on past performance or accurately determined current density figures for the metal in the electrolyte, at the temperature/flow/ambient conditions applicable to the structure, and should take into account long-term cathodic polarization and coating breakdown. These figures do not include any affects due to galvanic couples or stray currents.

historically in cathodic protection of steel in concrete, with many failures; and a similar conductive polymer wire anode used in buried applications.

*Group 2:* These anode materials have relatively low consumption (or wear) rates, and their dimensions generally do not change during consumption. They comprise MMO/Ti, platinized titanium, platinized niobium,

and conductive ceramic (and historically lead alloy and lead alloy with platinum micro electrodes) anodes used for submerged structures, ships, and power stations. Backfilled in carbonaceous backfill, MMO/Ti are also used for buried applications. MMO/Ti and conductive ceramic are widely used in cathodic protection of steel in concrete.

### 4.21.3.1 Group 1 Anodes

#### 4.21.3.1.1 Scrap steel

In some instances, a disused pipeline or other metal structure in close proximity to the project requiring cathodic protection may be used as the anode system. Reputedly, the first impressed-current jetty system in the United Kingdom used a keel of a scrap submarine as the anode. However, it is essential in cases of scrap steel or iron groundbeds to ensure that the steelwork is completely electrically continuous, and multiple cable connections to various parts of the groundbed must be used to ensure a sufficient life. Preferential corrosion can take place in the vicinity of cable connections, resulting in early electrical disconnection; hence the necessity for multiple connections. Scrap steel and iron are almost never used as anodes now.

#### 4.21.3.1.2 Graphite

Graphite anodes are usually resin-impregnated and supplied in standard lengths, for example, 65-mm dia. 1.2-m long; and 75-mm dia. 1.5-m long, with a length of cable (called the anode tail) fixed in one end. Graphite anodes were particularly common in early cathodic protection systems. However, they have been almost completely replaced by silicon-iron, the main reasons being (1) graphite tends to spall in use, particularly in chloride environments; and (2) it has a relatively low operating current density ( $10\text{--}20\text{ A m}^{-2}$ , Table 4). Thus, graphite anodes are very seldom used now, having been replaced with more efficient and reliable silicon-iron and MMO/Ti anodes.

#### 4.21.3.1.3 Silicon-iron

Silicon-iron anodes are generally supplied in standard sizes, for example, for solid castings 50 or 75 mm in dia. and 1.2 or 1.5 m in length and are complete with a cable tail. These anodes are made from cast iron with a high silicon content of 14–15%, together with small percentages of alloying elements such as chromium.

Anodes are available with enlarged heads within which the cable tails are terminated and encapsulated with resin and heat-shrink protective caps. They are available as ‘single ended’ or ‘double ended’ with, respectively, one cable connection at one end or one at each end. The ‘double ended’ anodes can be supplied in multiple anode strings with a single cable per string.

Centrifugally chill-cast tubular anodes are also available in diameters of 55–170 mm in lengths of 1.5 and 2.1 m with central connection of the cable. There are data that indicate the chill-cast anodes are more consistent in their performance, presumably

due to their finer and more consistent grain structure and that the central connection of the cables results in a higher utilization factor for the anode mass, as the end effects do not result in early consumption of the cable connection end(s).

Silicon-iron with 4.5% chrome has become the most common silicon-iron alloy used for impressed current anodes, but it should be used only when the chloride content of the electrolyte is significant. In soils with low chloride content, the tenacious oxide film, which forms on the chrome alloy and provides its low consumption rate in seawater and other chloride environments, can become highly resistive and lead to anode/groundbed apparent failure.

The main disadvantages of silicon-iron anodes are their weight and extreme brittleness, resulting in high transport costs and possible breakages from the foundry to the cathodic protection site, especially if this is overseas. This anode continues to be widely used, as its performance is very well established and is resilient to variation in operating conditions.

### 4.21.3.2 Group 2 Anodes

This group includes mixed metal-oxide coated titanium, platinized titanium, platinized niobium and tantalum, and conductive ceramic (and historically lead alloy and lead alloy with platinum micro electrodes) anodes used for submerged structures, ships, and power stations. Backfilled in carbonaceous backfill MMO/Ti are also used for buried applications. MMO/Ti and conductive ceramic are widely used in cathodic protection of steel in concrete.

#### 4.21.3.2.1 Platinized titanium

These anodes are usually in the form of a titanium rod, tube, or wire with an electroplated coating of platinum 2.5–5.0  $\mu\text{m}$  thick. Diameters are generally in the range 3–25 mm. In order to reduce the voltage drop in very long anodes, a copper-cored variety is available. Platinized titanium anodes may also be used in mesh or plain sheet form and can be fabricated to suit particular applications. Co-extruded platinum on titanium (and niobium), with or without a copper core is also available.

#### 4.21.3.2.2 Platinized niobium and tantalum

Niobium and tantalum can be used as substrate materials where environmental conditions dictate a higher driving voltage, for example, brackish water. Use is limited due to relatively high cost. Copper-cored materials are again available.

**Table 4** Operating characteristics of impressed-current anodes

<i>Anode material</i>	<i>Maximum working current density (<math>A\ m^{-2}</math>)</i>		<i>Nominal consumption (<math>kg\ (Ay)^{-1}</math>) except as stated in <math>mg\ (Ay)^{-1}</math></i>	
	<i>Soil</i>	<i>Seawater</i>	<i>Soil</i>	<i>Seawater</i>
Scrap steel	5–6	5–6	8	10
Scrap cast iron	5–6	5–6	6	8
Silicon–iron	10–30	10–30	0.5	0.5–1.0
Silicon–iron in carbonaceous backfill	10–100	N/A	0.1	N/A
Silicon–iron 4.5% Cr	10–30	10–100	<0.1	<0.5
Silicon–iron 4.5% Cr in carbonaceous backfill	10–100	10–100	<0.1	N/A
	Do not use in soils with no chlorides; will become highly resistive			
Graphite	10	10–20	0.25–2.5	0.5–5
Lead–silver alloy	N/A	100–200	N/A	0.025–0.10
Lead–silver alloy/Pt microelectrodes	N/A	200–1000	N/A	0.002–0.10
Pt/Ti	50–100	500–3000	Negligible in carbonaceous backfill	1.2–10 $mg\ (Ay)^{-1}$
Pt/Nb	N/A	500–3000	N/A	1.2–10 $mg\ (Ay)^{-1}$
MMO/Ti	50–100	500–1000	6–7 $mg\ (Ay)^{-1}$ in soils	1–2 $mg\ (Ay)^{-1}$ in seawater
			8–13 $mg\ (Ay)^{-1}$ in saline mud	2–4 $mg\ (Ay)^{-1}$ in brackish water
MMO/Ti in carbonaceous backfill	Negligible	500–1000	Negligible	N/A
<i>Anode material</i>	<i>Maximum working current density in concrete</i>		<i>Typical life in concrete</i>	
MMO/Ti mesh, strip, and ribbon surface-mounted and concrete-encased or cast into concrete	Short-term 220 $mA\ m^{-2}$		Subject to coating loading up to 100 years with a factor of safety (for nonuniform current density delivery) of 2.	
	Long-term 110 $mA\ m^{-2}$		Typical consumption for $IrO_2/Ta_2O_5$ coating 3.5–9 $mg\ (Ay)^{-1}$	
	Limited by acidification of concrete not anode parameters			
MMO/Ti tubular discrete anode drilled and mortared into concrete	800 $mA\ m^{-2}$		Subject to coating loading up to 100 years with a factor of safety (for nonuniform current density delivery) of 2.	
			Typical consumption for $IrO_2/Ta_2O_5$ coating 3.5–9 $mg\ (Ay)^{-1}$	
Conductive ceramic of monolithic $Ti_4O_7$ tubular discrete anode drilled and mortared into concrete	800 $mA\ m^{-2}$		Up to 100 years	
Conductive organic coating with carbon filler to concrete surface	20 $mA\ m^{-2}$		<15 years	
Arc- or flame-sprayed Zn to concrete surface	20 $mA\ m^{-2}$		<25 years	
MMO/Ti rod anodes in carbonaceous backfill drilled into concrete	800 $mA\ m^{-2}$ to carbonaceous backfill		<50 years subject to performance of carbonaceous backfill	
Ni-plated carbon fibers incorporated into a cementitious overlay	20 $mA\ m^{-2}$		<25 years	

Note: The above data are indicative only and based on a variety of sometimes conflicting data from numerous sources. Actual performance may vary due to particular electrolyte conditions.

#### 4.21.3.2.3 *Lead silver alloy with or without platinum microelectrodes*

The alloy is lead, together with 1–2% silver in rod or extruded section form with platinum microelectrodes inserted every 150 mm. The purpose of these microelectrodes, which take the form of pins, is to stabilize the formation of lead peroxide on the anode surface. These anodes have seen extended service as ship hull anodes and were favored by some designers for seawater cooling systems in power stations. They have been largely replaced with MMO/Ti anodes.

#### 4.21.3.2.4 *Mixed metal oxide-coated titanium (MMO/Ti)*

This anode material has become very widely used in seawater, in soils (generally backfilled in carbonaceous backfill), in saline muds (directly buried), and in concrete. The MMO compositions are held by some manufacturers to be proprietary as are the coating loading onto the titanium substrate. Some manufacturers declare their coatings to be  $\text{IrO}_2/\text{Ta}_2\text{O}_5$  mixtures and declare coating loadings and consumption rates. Others do not declare these critical parameters and the designer must rely on accelerated testing of samples from production batches to be secure in the design life.

Anodes for immersed and buried applications are available in tubular, rod, wire, and sheet forms, with tubular anodes having center-connected cables being widely used in strings as single anodes. Perforated and expanded Ti mesh and ribbon coated after perforation and expansion is widely used in carbonaceous backfill for the anode systems placed beneath tank bottoms during construction and in horizontal groundbeds. In deep-well groundbeds, tubular anodes are widely used in carbonaceous backfill.

MMO/Ti mesh, ribbon, strip, and tubular discrete anodes are widely used in cathodic protection of steel in concrete. The mesh and ribbon anodes are used surface-mounted within sprayed concrete overlays, or the ribbon and strip anodes have been used installed into cut slots in the concrete surface. Tubular anodes used as discrete point sources of current delivery are grouted into drilled holes in the concrete. Ribbon, in particular, is widely used in the application of cathodic protection to new construction reinforced concrete structures, in extreme environments or where its service is particularly critical, and the design life is beyond that which can be securely delivered by durable concrete design.

#### 4.21.3.3 *Other Anodes for Reinforced Concrete Applications*

Much cathodic protection of reinforced concrete is undertaken on existing structures, which have suffered corrosion due to chloride contamination, as part of concrete repair and strengthening works. Many of these systems require anodes to be installed on atmospherically exposed (above ground) concrete surfaces with the minimum of impact to the structure. Thus a whole range of anode systems has been developed for these applications since the mid-1970s in the United States and the late 1980s in Europe and elsewhere.

Some of these anode systems have been used briefly and either failed or not delivered their promised economic advantages to their developers. The former category includes a conductive polymer wire that proved to have failed approximately one-fifth of that claimed by its manufacturer and many conductive coatings and mastics that did not perform as claimed. In the latter category is an early bridge deck cathodic protection system from Ontario in Canada, which utilized cast silicon-iron ‘pancake anodes’ in a conductive overlay of coke breeze and mastic. Many of these systems performed very well, but they were not proprietary; they were heavy, and the physical properties of the coke-filled mastic were not ideal; they have fallen out of use.

Systems still in use include a limited number of good, well proven conductive coatings; a small range of products using proprietary nickel-coated carbon fibers in a carbonaceous mortar that can be low pressure-sprayed onto concrete as thick coating or a thin overlay; a proprietary MMO wire discrete anode in a carbon backfill; and conductive ceramic tubes of monolithic  $\text{Ti}_4\text{O}_7$  (registered name Ebonex).

Flame- and arc-sprayed zinc has been quite widely and successfully used in North America as an impressed-current anode in the colder northern regions and as a galvanic anode in the warmer regions such as Florida. A thermally sprayed Al–Zn–In alloy is a proprietary product with claimed advantages over zinc.

Galvanic anodes of cast zinc are available in a small range of proprietary forms precast into a high-pH lithium-dosed mortar, which is claimed to enhance the corrosion activity of the zinc. These systems were originally designed to be fitted into concrete repair areas to provide partial cathodic protection and principally to overcome the incipient corrosion cell between steel in new chloride-free repair mortar and the surrounding chloride-rich

original concrete; they fulfilled this function quite well. These systems, and developments from them, are now being promoted for cathodic protection of entire structures; it is uncertain whether they can deliver sufficient current to achieve the established protection criteria for steel in concrete, and it is almost impossible to monitor them effectively due to their direct connection to the reinforcement.

#### 4.21.4 Cathodic Protection of Buried Structures

##### 4.21.4.1 Soil or Water Resistivity

Soil resistivity measurements are carried out by the Wenner technique using commercially available instruments. Resistivity data are not only required to determine the anode resistance and size but also to indicate the probable corrosivity of the soil or water. In the case of a pipeline route, variations in soil resistivity may stimulate localized corrosion and

can cause long line currents; the area in the soil of lower resistivity is usually anodic (more negative) compared to that in the soil of higher resistivity. It is therefore impossible to give any precise ruling as to the rate at which corrosion will occur under any particular soil conditions, and the results of any survey must be taken as giving only a general indication of the probability of corrosion. More rigorous corrosion assessment surveys determine the soil types, the dissolved salts, and the presence of bacteria and critical species such as free sulfur or carbonaceous material, and produce a corrosivity index.

Chemical and other forms of industrial contamination of the soil can significantly influence soil resistivities and corrosion characteristics and it is essential to investigate these in detail where such contamination may have occurred (e.g., in the proximity of chemical plants, etc.).

A typical soil resistivity survey is shown in **Figure 2**. Soil resistivities will normally indicate whether a cathodic protection system is advisable in

**Figure 2** Typical soil resistivity survey.

principle and whether impressed-current or galvanic anode schemes in particular are preferable. It may, as a result of the survey, be considered desirable to apply protection to the whole line or to limit protection to certain areas of low soil resistivity or 'hot spots.'

The cost of cathodic protection to uncoated buried pipeline structures is relatively high and expense may prohibit complete protection, in which case the galvanic anodes may be installed in the lowest resistivity areas only – on the basis that these are likely to be the most corrosive. This was a situation regularly encountered by cathodic engineers in the 1950s and early 1960s in the United Kingdom and the United States when extending the life of old oil and water pipelines in particular. In the case of high-pressure gas and oil lines, it is normal practice (it is mandatory in many countries) to apply cathodic protection irrespective of the soil resistivity in view of the low cost when associated with modern pipeline coatings and the potential hazards that could occur should even a minute pinhole perforate the pipe. In such cases, a soil resistivity survey is required only in the probable areas of groundbeds in order to enable the size of the groundbed, rectifier voltage, etc. to be determined. The soil resistivity also determines the current output of magnesium or zinc anodes should this type of system be preferred.

The soil resistivity, measured using the Wenner technique, determines the average soil resistivity in a hemisphere to a depth equivalent to the distance between the pin spacings, and it must therefore be recognized that the design figure for groundbed design in a particular location may not be highly precise. At least 10% error in the calculated resistance may be expected.

Soil resistivity surveys are often impractical in built-up areas, but in such areas impressed-current cathodic protection is often avoided on account of the danger of interaction. Under such conditions, adequate protection can be achieved by installing magnesium anodes in the pipe trench should the soil resistivity measurements made when the trench is opened indicate that this is necessary.

#### 4.21.4.2 Impressed-Current Design

Designs can be prepared once soil resistivities and groundbed locations have been determined. [Figure 3](#) illustrates typical installations. Design steps have been summarized in [Table 3](#) and are summarized below for a simple pipeline.

1. Select the current density to be applied from the results of cathodic protection tests and from any available data. On pipeline structures, attenuation is always a factor and the average current density is determined from the attenuation curves, or the total current to give protection at the points most distant from the drainage point may be computed.
2. Compute the total current requirement to achieve the required current density (total current = current density  $\times$  superficial surface area). Undertake this for initial, mean, and final estimated coating conditions.
3. Determine the optimum spacing between groundbeds based on availability of electrical power supplies and the classical attenuation formulae.
4. Based on the most negative permitted pipe/soil potential near the installation and the necessary potential change for the attenuation formula, determine the maximum permitted impact of the anode tension hill and thus calculate the distance between groundbed and pipeline.
5. Design the groundbed system in accordance with classical electrode-to-remote-earth resistance formulae for the selected anode groundbed type (continuous horizontal, deep well, multiple shallow boreholes).
6. Design the DC wiring system for the most economical cable size in accordance with standard electrical practices and then calculate the total IR (ohmic) drop in the circuit.
7. Select transformer rectifier voltage and current outputs.
8. Design the electrical circuits, fittings, and switchgear in accordance with standard electrical practice.
9. Select the location of cathodic protection test stations.
10. Prepare project drawings and specifications.

The total circuit resistance of a groundbed installation includes cable resistance, resistance of the anode to the carbonaceous backfill, and resistance to earth of the backfill column itself. In the case of seawater installations, the anode resistance is between the seawater and the anode surface only. The back emf between the anode and cathode should be included in the calculations to determine the transformer rectifier output voltage. It is normal for personnel and animal safety to limit the output voltage of transformer rectifiers to 48 V (lower if possible), and it is good practice in areas of third-party pipelines and structures to limit the individual installations to a low output current in the range 5–25A.

#### 4.21.4.3 Anode Backfill

The carbonaceous backfill surrounding an anode is essential and serves a number of functions, as given below for example:

1. Being of low resistivity, it has the effect of increasing the anode size with resulting reduction in resistance to earth.
2. Most of the current is transmitted to the backfill from the anode by direct contact, so that the greater part of material consumption is on the outer edges of the backfill column, enabling the anodes themselves to have an increased life.

The backfill composition may be of several types, varying from coke breeze to manmade graphite particles. A coke-breeze backfill consists of high temperature-fired coke breeze or calcined petroleum coke with not less than 95% dry weight of carbon with a maximum resistivity of 50  $\Omega$  cm when lightly tamped, dry, and prior to the addition of lime. A typical specification requires that 100% will pass through a 16-mm aperture, 90% will pass through an 8-mm aperture, and not more than 15% will pass through a 1-mm aperture, and that the coke breeze should be thoroughly mixed with 5% by weight of slaked lime.

#### 4.21.4.4 Resistance of Groundbeds

The resistance of groundbeds for protection of pipelines or anodes for protection of jetties or other

seawater structures is usually calculated in accordance with the formulae originally developed by Dwight. However, the following abridged formulae are normally used and are sufficient for all practical purposes.

Resistance of a single horizontal rod anode:

$$R_H = \frac{\rho}{2\pi L} \left\{ \ln \frac{4L}{d} - 1 \right\}$$

Resistance of a single vertical rod anode:

$$R_V = \frac{\rho}{2\pi L} \left\{ \ln \frac{8L}{d} - 1 \right\}$$

where  $R_H$  is the resistance of a single horizontal anode ( $\Omega$ ),  $R_V$  is the resistance of a single vertical anode ( $\Omega$ ),  $\rho$  is the resistivity ( $\Omega$  cm) of soil or backfill,  $L$  is the length of the rod (cm), and  $d$  is the diameter of the rod (cm).

Where anodes are installed in special backfill, two series resistances are present – anode to backfill and backfill to soil. In practice, and with coke breeze backfill, a single calculation based upon the dimensions of the backfill column and soil resistivity is satisfactory.

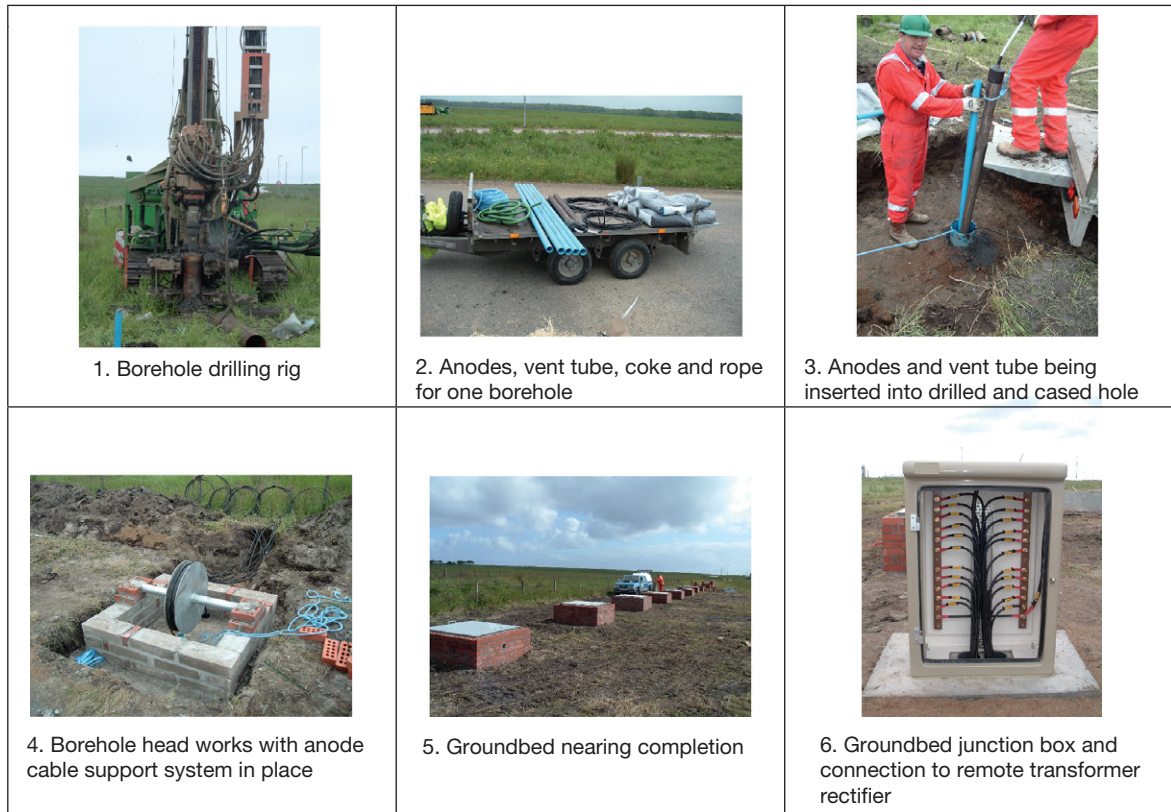

Resistances of several anodes in parallel can be calculated by the formula

$$R = \frac{\rho}{2\pi NL} \left\{ \ln \frac{8L}{d} - 1 + \frac{2L}{S} \ln 0.656N \right\}$$

where  $R$  is the resistance to earth ( $\Omega$ ) of the vertical anodes in parallel,  $r$  is the soil resistivity ( $\Omega$  cm),  $N$  is the number of anodes in parallel,  $L$  is length of the anode (cm),  $d$  is the diameter of the anode (cm), and  $S$  is the anode spacing (cm).

**Figure 3** Continued. Deep-well installation. (a) Groundbeds for buried pipes using impressed current. (b) Groundbed installation using multiple shallow boreholes (above a rock substrata) utilizing silicon-iron anodes with Kynar-insulated polyethylene-sheathed cable (note the large-diameter cable support system) and calcined petroleum coke. The boreholes were sacrificial steel lined except for the top 5 m, which was plastic pipe lined. Courtesy of R & R Corrosion Ltd and Corrosion Control Affiliates Ltd. (c) Deep-well installation.

#### 4.21.4.4.1 Deep-well groundbeds

This type of groundbed is illustrated in [Figure 3](#) and is normally employed where the surface soil resistivities are very high, for example, in desert areas. They have the advantage of taking up little surface area and can be installed, in the case of a pipeline project, in the existing pipeline wayleave. They have the further advantage of minimizing interaction on foreign structures. Abandoned oil or water wells can sometimes be used for this purpose. The type of groundbed can be of the design illustrated, or alternatively can be assembled on the surface in a steel case and lowered down a suitably drilled hole.

#### 4.21.4.4.2 Determining rectifier voltage

In determining the rectifier voltage, the following must be taken into consideration:

1. The groundbed resistance, as previously explained; this will generally be the major resistance in the calculation.
2. Back voltage polarization between groundbed and pipeline. In the case of graphite, MMO/Ti and silicon-iron anodes in carbonaceous backfill, an allowance of 2 V is normally used. This back voltage is that which exists between the anodes and the structure in opposition to the applied voltage.
3. Resistance to earth of the pipeline at the groundbed location. This resistance to earth depends on the quality of the pipeline coating. The better the coating, the higher the resistance; generally the pipeline resistance will be a lower order than the groundbed resistance.
4. Resistance of the cable from the pipeline to the power source and from the power source to and along the anodes comprising the groundbed. This cable resistance must be determined from the standard tables supplied by the cable manufacturer.

Once the total circuit resistance and the required current output are known, applying Ohm's law will allow the transformer rectifier or power source voltage to be calculated.

#### 4.21.4.5 Attenuation

When cathodic protection is applied to an underground metal structure, the greatest effect on the pipe-to-soil potential is at the drainage point. This effect decreases, or attenuates, as the distance from the drainage point increases.

Complex structures such as tank farms, tank bottoms, and marine installations have complicated

attenuation patterns and it is not feasible to use complex equations to determine the effect. This must be determined by a current drain test, by practical experience, or by mathematical modeling. For pipelines, the attenuation depends on the linear resistance of the pipe, coating resistance, and to some extent the resistivity of the soil. Connections to foreign structures and the method of termination of the line also affect the attenuation. There are relatively simple classical attenuation formulae for pipelines.

#### 4.21.4.5.1 Field measurements

In order to obtain the actual field attenuation characteristics, a pipeline can be placed under temporary cathodic protection and measurements made under different cathodic protection current conditions. A 'natural' pipe-to-soil potential survey should be made over the length of the line to which cathodic protection is to be applied. These static measurements supply a reference level on which to base the subsequent readings. After the natural survey is completed, measurements are made at the same test points with the temporary cathodic protection system installed. The pipe-to-soil potential should be read twice, once with the test current ON and once with the current Instant OFF (potential measured ideally between 0.2 and 1s after switch OFF). The data are then plotted as shown in [Figure 4](#).

The horizontal scale is the distance along the pipeline from the drainage point 0, and the vertical scale is the pipe-to-soil potential. The polarization potential and the driving voltage may then be plotted on semilogarithmic paper using the same horizontal scale ([Figure 5](#)). Attenuation is more rapid in low-resistivity soils or with less good coatings than in high-resistivity soils or with good coatings. If nonuniform conditions prevail, the curves will not be

**Figure 4** Longitudinal distribution potential on pipeline. Note: 'Stations' refer to points at which the potential is measured.

**Figure 5** Attenuation curve on pipeline shown in Figure 4. Upper curve shows the ON-static values (which include IR drop errors) and the lower curve shows the instant OFF-static values.

**Figure 6** Attenuation curves for bare pipe and poorly coated pipe in similar soils. Note P/S (pipe/soil) potentials are negative.

straight lines as shown in Figure 5, in which the lines in the left of the figure are typically curved as a result of low resistance.

#### 4.21.4.5.2 Measurement between drainage points

Figure 6 shows typical curves for a bare pipe and a poorly coated pipe in similar soils, and it can be seen that the former has a much steeper attenuation curve than the latter. Figure 7 shows how the desired protection level of potential has been attained between widely spaced drainage points, in which the dotted curves show the attenuation curves for the individual drainage points.

#### 4.21.4.5.3 Coating resistance

The electrical resistance of a coating on a pipeline will depend upon the effectiveness of its initial application to the metal and on its condition at the time of

**Figure 7** Attenuation curves for multiple drainage points of moderate size.

testing; absorption of moisture may decrease the resistance by as little as 10% during the initial few years. The leakage resistance of a given section of pipeline may be determined as follows:

1. Applying temporary cathodic protection to the pipeline and measuring the pipe-to-soil potential for a given driving voltage of various test points spaced along the pipeline from the drainage point. The drainage current should also be measured.
2. Calculating the attenuation constant.
3. Measuring or calculating the longitudinal resistance of the pipeline. The resistance can be calculated from

$$R = \frac{2\rho l}{dt}$$

where  $\rho$  is the specific resistivity,  $l$  is the length of the pipeline,  $d$  is the diameter, and  $t$  is the thickness in appropriate and consistent units.

#### 4.21.4.5.4 Types of cable for anode installations

Cables used for anode groundbeds must be well insulated and suited to operational conditions. Mechanical damage from sharp coke particles and chemical attack from generated gases (e.g., chlorine) may be prevented by the use of polytetrafluoroethylene (PTFE) sleeving or a similar material. Alternatively, chemically resistant cable insulation such as cross-linked polyvinylidene fluoride (Kynar) may be used along with high molecular weight polyethylene (HMWPE) protective sheath. This type of cable is essential for deep-well groundbeds where nascent chlorine generation and highly acidic conditions may have to be tolerated. However, caution should be exercised when using Kynar-insulated cable, as the Kynar is brittle at low temperatures and may crack particularly if bent through a small radius.

For less severe applications, cross-linked polyethylene (XLPE) insulated and XLPE-sheathed cables may be sufficiently resistive to the anode reaction products.

#### **4.21.4.6 Power Sources for Cathodic Protection**

Where AC supplies exist, transformer rectifiers are the most economical source of DC for cathodic protection systems. A typical output for a well coated cross-country pipeline in the United Kingdom would be 5 A, 48 V. In the case of seawater jetties, where the voltage required is usually low because of the lower seawater resistivity, a typical rectifier size for a major installation would be 500 A, 18 V. For oil or gas terminals, offshore structures, and loading platforms where an incendiary sparking hazard exists, it is usual to locate the transformer rectifiers remote from hazardous areas or to employ certified flameproof or intrinsically safe rectifiers to overcome any possibility of explosion hazard during operation of the equipment.

Where ac supplies do not exist, other sources of power can be used such as DC generators, either diesel or gas driven. Alternatively, thermoelectric generators may be considered if the power requirement is relatively low, as they are only available in relatively small outputs. They may have the advantage of being able to be completely self-contained since they can be powered by taking off some of the gas that passes through the pipeline. Photovoltaic (PV) cells or wind-driven generators and battery systems have been successfully used for the protection of well coated pipelines and for reinforced concrete systems. However, as they tend to be used in remote locations which are short of distributed electrical power, there is a history of them being stolen.

### **4.21.5 Seawater-Cooled Circulating Water Systems**

#### **4.21.5.1 Galvanic Anodes**

The use of galvanic anodes in circulating water systems is limited to the application of cathodic protection to stop gates, coarse screens, and other plants that are readily accessible so that the anodes can be replaced when they are consumed. Such anodes are not normally used in condensers, pumps, and auxiliary coolers for the following reasons:

1. Frequent replacement is required with consequent shutdown of the plant concerned.

2. Anodes are required to be very large to provide the current density necessary with a reasonable life. Anodes can interfere with the water flow.
3. Corrosion products or dislodged anode particles from anodes can cause tube blockage and subsequent failure.

#### **4.21.5.2 Impressed-Current Anodes**

Anodes for the internal protection of the plant are normally of MMO/Ti (historically platinized titanium or lead alloy).

##### **4.21.5.2.1 Continuous anodes**

They consist of considerable lengths of relatively flexible copper-cored material which can be contoured to suit restricted spaces or to distribute current in a localized fashion. Typically, they may be used in water boxes at a nonferrous tube-plate/ferrous water box junction. Anode terminations pass through the water box via insulating entry points, and the anodes are supported on insulators within the box. Anode-cathode distance must be such as to prevent the anode becoming engulfed in calcareous deposit that forms on the cathode.

##### **4.21.5.2.2 Rod anodes**

These consist of solid or copper-cored titanium rod, portions of which can be platinized. They range from 6 to 25 mm in diameter and are normally supplied preassembled in a steel or polymer mount ready for screwing into prepared bosses on the plant under protection. Electrical connections are made via cables in the usual way. The anodes are spaced to give even current distribution. Anodes are typically designed to have sufficient mechanical strength to withstand being used as foot and hand holds, particularly in water boxes.

##### **4.21.5.2.3 Tubular anodes**

Tubular anodes are supplied in diameters between 12.5 and 32 mm and have been designed for installations where water conditions on the plant under protection are known to be turbulent. The tubular anode has a number of holes drilled in the active portion of the anode, and the nonactive portion is filled with sand to act as a damping agent. As in the case of rod anodes, they are supplied complete with mounts ready for installation in the prepared bosses on the plant under protection. They are particularly suitable for the internal protection of pump casings and the internal protection of pipelines carrying salt water or other low-resistivity liquids.

More recently, other methods have been used to assess anodes for their ability to withstand the fatigue loadings from eddy shedding which can occur in relatively high electrolyte flow rates.

#### 4.21.5.3 Impressed-Current Systems

Impressed-current systems for power stations are somewhat more sophisticated than those required for pipelines or marine structures inasmuch that a large number of items of the plant, with a wide range of current requirements, are often protected by one multichannel transformer rectifier. Each section of every water box requires one or more anodes in order to provide even current distribution. In the case of a large circulating water pump, as many as 30 anodes may be required to provide the necessary current distribution. Three types of system should be considered as follows:

1. Manually controlled.
2. Automatically thyristor-controlled.
3. Automatically controlled modular.

##### 4.21.5.3.1 Manually controlled system

A manually controlled system comprises one or more transformer-rectifiers each with its associated control panels which supply the DC to the various anodes installed in the water box spaces. Each transformer rectifier is provided with its own control panel, wherein each anode is provided with a fuse, shunt, and variable resistor. These enable the current to each anode to be adjusted as required. Reference electrodes and test connections should be provided in order to monitor the steel/electrolyte potential values achieved by the cathodic protection system. In the case of a major power station, one transformer rectifier and associated control panel might be provided for separate protection of screens, circulating water pumps, and for each main condenser and associated equipment.

When coolers or condensers are shut down but remain full of water, the amount of current required to maintain satisfactory cathodic protection is considerably reduced. If the current is not reduced, overprotection occurs and excessive amounts of chlorine can be generated which would tend to accumulate in the upper section of the water boxes causing considerable corrosion, not only to the water boxes but also possibly to the tubes. To ensure against this, a standby condition should be included on the control panel which effectively reduces the current required under shutdown

conditions. This control is effected by a limit switch fitted to the outlet valve of the condenser or cooler concerned. It is impossible to determine the exact requirements for the protection of circulating water systems in advance, and it is normal to adjust the current to provide protection during commissioning.

These simple resistor-controlled systems have lost favor as the costs of more sophisticated electronic control systems have dropped and have become more available. However, the principle of simple transformer rectifiers and resistive-controlled individual anode outputs is occasionally used in other applications.

##### 4.21.5.3.2 Automatic potential controlled system

This method is basically the same as the manual system. However, the current output of the transformer rectifier is automatically maintained at a level to ensure satisfactory cathodic protection under all operating conditions. This is achieved by means of sensing reference electrodes located in the main item of the plant, for example, main condenser, which feeds back steel/electrolyte/reference electrode potential data to an automatic control device within the transformer rectifier. The control device is preset at the required potential, and any incoming signals are compared with this preset potential and the level of current either raised or lowered until the incoming signal agrees with that of the preset potential in the automatic device.

It is also usual to fit additional (monitoring) reference electrodes and test connections as an independent check on the performance of sensing (controlling) electrodes.

##### 4.21.5.3.3 Automatically controlled modular system

This method employs one large, manually controlled transformer rectifier used in conjunction with a number of modular controlled outputs either within the main cabinet or in smaller cabinets located adjacent to each item of the plant requiring protection. The main transformer rectifier feeds DC to each of the module units, and the modular unit provides the exact amount of current required by the item of the plant in question.

#### 4.21.6 Marine Structures

The method of applying cathodic protection to immersed structures will depend on several factors including the following:

1. Size of the project.
2. Availability of power supply.
3. Possibility of problems from interaction.
4. Necessity for safety from spark hazard.
5. Expected economic life of the system.

**Figures 8(a) and 8(b)** give an indication of the relative numbers of anodes that may be involved for galvanic anode and impressed-current systems.

However, the offshore experience in severe environments such as the North Sea is clear. A significant number of impressed-current systems designed in the 1970s and early 1980s failed due to inadequate design, insufficient mechanical integrity of the anode and monitoring system supports, and even gross errors in surface area calculations. These included systems with anodes as inferred in **Figure 8(c)**, which were

**Figure 8** Protection of offshore oil drilling/production platform. (a) With galvanic aluminum anodes and (b) with impressed current using MMO/Ti, platinized titanium, or platinized niobium anodes. (Compare the large number of anodes used in (a) with the small number used in (b)). installed using small-diameter anode riser tubes to carry the anode and its cable to the positions as shown. Many such systems were the subject of major retrofits with galvanic anodes. Some notable impressed-current systems were designed in the 1980s and later have been made reliable, but the costs of the design and implementation of such reliable systems are high (Figure 9).

Current-density requirements depend on the environment, galvanic effects, velocities, and other factors influencing polarization. In the absence of galvanic influences or other secondary effects,  $60 \text{ mA m}^{-2}$  may be sufficient in seawater to maintain adequate polarization for protection once it has been achieved; it is, however, normally necessary to apply  $120\text{--}250 \text{ mA m}^{-2}$  to achieve initial polarization within a reasonable period, and if rapid protection is required, current densities as high as  $300 \text{ mA m}^{-2}$  may be applied.

(a)

(b)

Courtesy of Global Cathodic Protection Ltd and B S Wyatt.

Anodes placed on the seabed remote from the structure can be considered, but these installations may have problems due to damage to the connecting cable by ships' anchors, etc., and, more importantly, there have been serious interaction problems in the North Sea from such seabed remote anodes to the incoming production and outgoing export pipelines/risers which are normally electrically isolated from the jacket due to different cathodic protection performance characteristics.

The calculation of rectifier voltage/anode resistance is exactly as described for impressed-current pipeline installations except that the voltage required is very small because of the low resistance of the electrolyte: normally  $25\text{--}35 \Omega \text{ cm}$  for typical seawater. In the assessment of seawater resistivity, it should be remembered that the resistivity increases significantly with decreasing temperature.

For cathodic protection of sheet steel piling, the impressed-current or galvanic anodes are normally mounted within the re-entrants of the piles to prevent mechanical damage by berthing ships, dredging, etc. (Figure 10).

As in the case of power stations, where there is known to be considerable variation in operating conditions due to tidal changes, or variations in salinity of estuary waters, automatic control of impressed-current systems is generally desirable. For such systems, the current output of the transformer rectifier is controlled by the use of thyristor-controlled rectifiers. Sensing electrodes are permanently installed on selected piles, which transmit the steel/seawater/electrode potential back to the controlling device. This type of system enables the most appropriate current to be provided under all operating conditions in order to deliver uniform levels of protection.

#### 4.21.7 Ships

Cathodic protection is effectively supplied to ships' external hulls and also to the tanks of oil tankers and other vessels wherein seawater is used for ballast or other purposes. For internal protection, galvanic anodes of the zinc or aluminum are normally employed; magnesium and impressed-current anodes are not used in tanks, which can contain explosive gases due to the incendiary spark hazards. Impressed current can also generate chlorine inside closed water spaces; both magnesium and impressed current can also generate hydrogen gas, so both should only be used with extreme caution and appropriate

**Figure 10** (a) Sheet steel piling impressed-current installation. More modern installations would utilize MMO/Ti anodes and their mounting system would include a dielectric shield that would, subject to anode current rating, extend the full width of the in pan and extend above and below the anode. (b) Galvanic anode (Al–Zn–In) system to sheet steel piled wall and associated fenders at extreme low tide. Note that anodes to piles are within the in-pans and all anodes are behind the fender line. The coated piles were the subject of accelerated low water corrosion (ALWC), a form of microbial corrosion common in ports and harbors, which is able to cause local section loss at c. 2 mm/side per year. The anodes are normally fully immersed; the extended anode cores allow critical structural support welds to be made above the water for lower cost and more secure quality. Courtesy of B. S. Wyatt Corrosion Control.

precautions in confined spaces. External hulls can be protected either by galvanic or impressed-current methods, although impressed current is now preferred at least for larger vessels (**Figure 11**). Anodes of MMO/Ti, platinized titanium, or lead–silver alloy with platinum bielectrodes, are mounted on the hull below the water line and can be designed to have current outputs of up to 200 A. In vessels such as tankers, where there may be access problems, the

anodes are located at both the stern and the forward end of the ship. All cable or other entries through the hull plate must be carefully designed using a special cofferdam, and the complete system has to be submitted to the ship approval authorities prior to installation. Because of the rapid variation in electrolyte conditions during passage of the vessels and the need to both maintain uniform protection levels and prevent overprotection and damage to the specialist marine coatings, all schemes for ships are automatically potentially controlled.

The transformer rectifiers typically contain thyristor-controlled rectifiers and operate in a manner similar to that described for power stations.

#### 4.21.8 Water Storage Tanks

Galvanic anodes are of limited application because of accumulation of anode corrosion products and also, in many cases, of high water resistivity.

Impressed-current systems are normally based upon anodes of MMO/Ti, platinized titanium, or platinized niobium. The method of anode installation is usually by suspension. The anode configuration and number must be such as to ensure uniform current distribution. Considerable use is made of wire-type platinized titanium and niobium anodes, which offer minimal weight and relative ease of mounting/suspension.

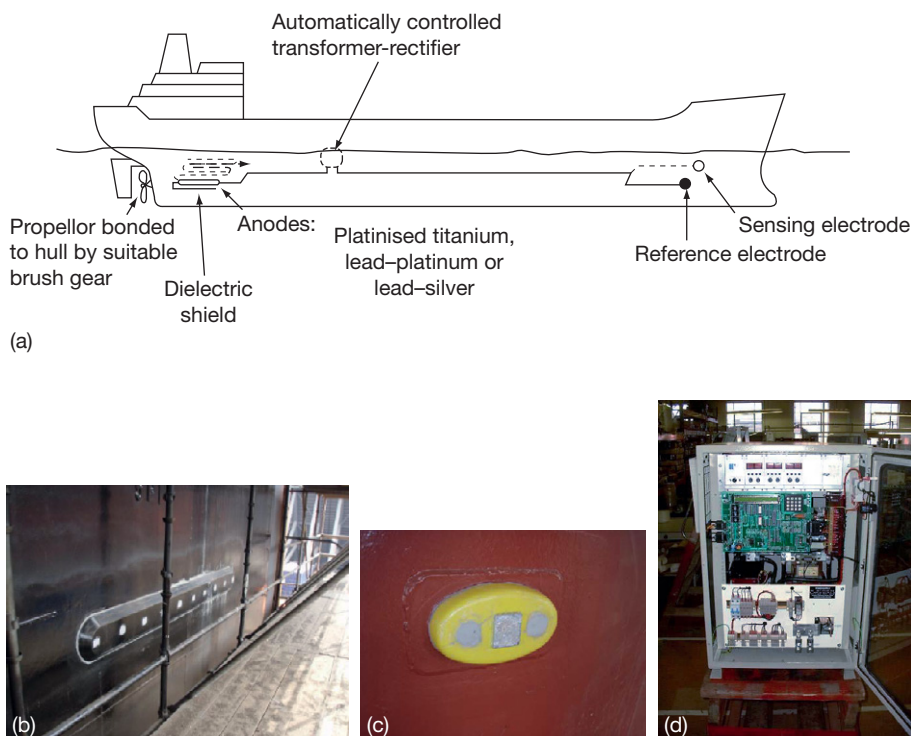

Coatings are normally employed for water storage tanks, which result in relatively low total current requirements in association with the current densities given in **Table 4**.

#### 4.21.9 Internal Protection of Pipelines

The current spread from an internally immersed anode is directly related to pipe size and the resistivity and temperature of the water; with seawater having a resistivity of  $\sim 30 \Omega \text{ cm}$ , anodes are normally required within a 250-mm-diameter pipe at  $\sim 1\text{-m}$  centers and in the case of a 760-mm-diameter pipe at  $\sim 3\text{-m}$  centers (**Figure 12**). Small bore, high resistivities, and high electrolyte velocities further reduce the anode spacing.

Cathodic protection is therefore normally practicable only in large-bore pipes carrying salt water or relatively low-resistivity river water used for cooling inland power stations or chemical plants. Under special circumstances, however, it has been found necessary to use cathodic protection in relatively high-resistivity

**Figure 11** (a) Impressed-current cathodic protection system for ships. Larger vessels would also have bow-mounted anodes which would normally be smaller, recessed, and round to prevent damage to them. Anodes of MMO/Ti are now often used. The dielectric shields around the anodes are generally high-build epoxy coatings selected for their very good cathodic disbondment resistance and high (electrical) dielectric (insulating) properties. (b) Ship's impressed-current anode installed on the hull (anode elements masked during coating). Courtesy of Corpro Companies Europe Ltd. (c) Ship's reference electrode. **Figure 12** Internal protection of pipeline. Typical current density (seawater) =  $200 \text{ mA m}^{-2}$  to bare steel at low flow rates: significantly greater for polarization at higher flow rates.

fresh water, particularly where microbial corrosion has been present; in these instances, anodes have been run longitudinally down the entire length of the pipe. In such applications, particular attention is required to avoid fatigue failures of the anode supports due to eddy shedding within the water flow.

#### 4.21.10 Cathodic Protection of Steel in Concrete

Cathodic protection of steel in concrete has developed from limited applications to buried reinforced and prestressed concrete pipelines in the 1950s, through

small-scale trials on bridge structure in the 1960s, to a major industry in the twenty-first century. Cathodic protection is applied to both new construction (prior to corrosion initiation) and to existing structures that have suffered corrosion initiation and often have suffered considerable corrosion damage to the steel and cracking and spalling of the cover concrete.

Due to the nature of reinforced concrete structures, their cathodic protection systems are significantly different from other applications. The anode–cathode spacings are typically in the range 15–100 mm in concrete compared with 5–250 m between anodes/groundbeds to pipelines in soil or 300 mm or more between anodes and steel in seawater. Further, the concrete electrolyte (actually the cement paste gel that binds the sand and stone aggregate into an effective structural composite) has an electrical resistivity that is high compared with most soils, typically in the range 20 000–200 000  $\Omega$  cm. This results in very considerable IR voltage drop errors in concrete, greater even than those in buried-pipeline applications.

In addition, whereas most steel in soil or waters cathodic protection applications the electrolyte is near neutral, in concrete the pH is typically greater than 10.5. Thus, the protection criteria for steel in concrete differ considerably from those for steel in soils or waters. The absolute protection criterion is accepted as  $-720$  mV with respect to Ag/AgCl/0.5 M KCl (equivalent to  $-720$  mV with respect to Ag/AgCl/seawater) compared with  $-800$  mV for steel in aerobic soils or waters with respect to Ag/AgCl/seawater (or  $-850$  mV with respect to Cu/CuSO<sub>4</sub> saturated) or  $-900$  mV with respect to Ag/AgCl/seawater in the presence of active microbial corrosion. Potential shift, more normally, due to time-dependent changes in depolarized potentials; potential decay values of 100 mV over 24 h or 150 mV total decay over longer periods are the normally used criteria for atmospherically exposed concrete. These may be compared with the 300 mV potential shift criterion favored by some North American pipeliners.

Current densities for actively corroding steel in concrete are typically in the range 2–20 mA m<sup>-2</sup> (of steel in temperate climates), and for preinitiation (where the purpose of the cathodic polarization is to maintain the passivity of the steel in the concrete even at high chloride concentrations), they are typically in the range 0.2–2 mA m<sup>-2</sup>. Typical applications of cathodic protection to steel in concrete are shown in [Figure 13](#).

Anodes used in cathodic protection of steel in concrete are summarized in [Table 4](#). Power supplies are typically quite complex multichannel transformer

rectifiers, typically with individual channel outputs <10 A and <18 V (for complex projects, some individual channels may be only 0.5 A, 12 V, whereas for larger more uniform zones on the same project, they may be 5 or 10 A, 12 V) and due to the complex nature of such structures, with their varying steel densities and varying exposure to chlorides, each channel may be associated with several monitoring channels of test connections associated with both permanently installed reference electrodes and pseudo (reference) electrodes or potential decay probes.

Owing to the complexity of these systems, the large number of dc power channels, the even greater number of monitoring channels, and the need to collect potential decay data over periods often in excess of 72 h, it is normal for cathodic protection of reinforcement systems to be fitted with data logging and remote monitoring systems using telephone landline or GSM modems.

#### 4.21.11 Economics

Cathodic protection design involves achieving an economic balance between installation costs, maintenance costs, initial cost of power units, and power consumption. Because both the cost of the rectifier and the cost of the electric power consumed are contingent on the operating voltage of the system, it is desirable to keep the operating voltage as low as possible; for this reason, a low-resistance anode system is desirable when it is economically feasible. Further, there are higher risks to personnel and animals at higher voltages. Simulated cost curves plotted on a cost versus the number of anodes in a groundbed for an assumed set of conditions are shown in [Figures 14](#) and [15](#). [Figure 14](#) is based on installed capital costs only, whereas [Figure 15](#) is the minimum annual cost.

#### 4.21.12 Recent Developments

##### 4.21.12.1 Galvanic Anode Systems

As the general standard of protective coatings has improved (materials, application, and construction standards), the use of galvanic anodes has extended to soil of *c.* 10 000  $\Omega$  cm or more for well-coated buried pipelines. By using anodes in extruded or continuously cast and hot rolled ‘ribbon’ form and placing them in the pipeline trench, they can be effective in soils of high resistivity.

The use of high-strength steels and alloys in offshore oil and gas developments and in submarines occasionally results in structures, pipelines, or vessels

that are subject to hydrogen embrittlement and which cannot be subject to the more normal range of protection criteria of  $-800$  mV (or  $-900$  mV in the presence of microbial corrosion) to  $-1050$  mV with respect to a silver/silver chloride/seawater. Some high-yield materials, when subjected to significant stress levels, may have safe cathodic protection potential limits as positive as  $-780$  mV; other materials may be safe at potentials in the range  $-800$  to  $-900$  mV. In order to achieve safe protection of such materials, two different approaches have emerged. One that has been quite widely used on offshore oil and gas facilities is the use of carefully selected Schottky barrier rectifiers

(SBRs), which are inserted between the normal Al–Zn–In anode and the high-strength steel or alloy structure and which limit the polarized metal/electrolyte potential level to a predetermined safe limit. The other is an Al–Zn–Ga anode alloy that operates at a closed circuit potential which is safe for some grades of high-yield steel; this is less extensively used than the SBR approach, but has the benefit of simplicity if reliable for long-term use.

With the developments in very high dielectric strength coatings, in particular the three-layer polyethylene or polypropylene (a thin fusion-bonded epoxy coating followed by an adhesive followed by

**Figure 15** Variation of minimum annual cost with number of anodes installed.

an extruded thick-wall tube or coating over the pipe), small coating defects on pipelines are vulnerable to very rapid corrosion due to ac current discharge/pickup at the coating defects. There have been significant and unexpected gas and oil pipeline failures/major section loss by pitting due to ac corrosion. Many such pipelines, while nominally protected with impressed current (at extremely low current densities, which present their own control and monitoring difficulties), are being fitted with extensive networks of zinc or magnesium ribbon anodes primarily for electrical earthing purposes. The AC currents are collected/discharged preferentially via these galvanic anode systems.

The development of large-scale galvanic anode retrofit anode systems for extending the design life of offshore jackets or pipelines has resulted in very large bracelet anode and anode arrays on tubes and sleds being designed. Most of these systems have been in Al–Zn anodes, but some very successful systems with design lives (that have been delivered in practice) have used magnesium anodes on pipe arrays and sleds, remote from the structure being protected, with the design of the anode resistance, the connecting cable resistance, and the distance between the anode and the structure being carefully balanced to prevent exceeding the normal  $-1050$  mV steel/sea-water potential limit with respect to silver/silver chloride even when using anode material with a closed circuit potential of  $-1500$  mV.

There have been major changes in the production/supply chain for magnesium anodes (most Mg was produced from seawater using the Dow process and Dow Chemical Corporation in the United States were the major international producers of Mg anodes until the 1990s). Since the 1990s, there has been the development of many small-scale producers, mainly in China, using a smelting route of production that has led to alloys, which, although are clearly within accepted chemical composition limits, perform below their anticipated efficiency or  $\text{Ah kg}^{-1}$  capacity. It is now a good practice to test each batch of magnesium anodes for its capacity before purchase/sale. This does not mean that the alloys or anodes are of deliberate or accidental poor quality; it means that either metallurgical or trace element issues which are not presently well understood and were previously uniform are now variable and can significantly affect anode performance.

#### 4.21.12.2 Impressed-Current Anodes

Anodes of scrap steel, graphite, and lead alloys have virtually ceased to be used. Silicon–iron is still widely

used due its robust and secure performance. MMO/Ti anodes have developed immensely in the late 1990s and into the twenty-first century; their use in cathodic protection of steel in concrete is extensive, but they have also replaced other anode materials in many applications in soils and waters.

Specific anodes for cathodic protection of steel in atmospherically exposed (above ground) concrete have been developed; some have failed to deliver their early claimed promise. Pt/Ti and Pt/Nb anodes are still used but are becoming specialist items as MMO/Ti anodes take more market share due to near-equivalent performance (better in some respects) and lower cost.

#### 4.21.12.3 Power Sources for Cathodic Protection

The most commonly used cathodic protection power supplies, that is, transformer rectifiers, for the traditional applications of cathodic protection of steel in soils and waters have not changed significantly in the period 1990–2009 except more have been supplemented with elements of remote monitoring and/or remote control. Units manufactured in Europe are now almost exclusively thyristor-controlled silicon diode rectifiers with improved efficiencies and service life expectancies than the old selenium rectifiers and transductor, rotary transformer or tap changed transformer controls that were used in the 1960s through the 1980s.

Switch-mode power supplies offer possible advantages of small size and lower cost. Some remain concerned by their apparent fragility in response to the typical surge and spike conditions that cathodic protection power supplies often are subject to.

Microelectronics has allowed the design and reliable manufacture of distributed power supplies of the type that were pioneered for power station cooling water cathodic protection in the early 1970s. However, there have been many examples of small suppliers dedicated to small-volume cathodic protection applications producing ‘clever’ integrated cathodic protection power supplies and data logging/remote monitoring systems, which have been unreliable and incapable of maintenance once the producing company ceased to trade or even the individual designer left the company. There is great merit in the use of industry-standard monitoring and control hardware and software that can be purchased from many sources and is produced in such volume as to reasonably assure adequate development, testing, and ongoing upgrades and software support.

Reinforced concrete cathodic protection has forced the pace in development of multichannel, heavily monitored power supplies with integrated monitoring and control.

#### **4.21.12.3.1 Solar and wind power**

With improved technology and production methods, considerable use is being made of solar power in remote locations. The output of PV arrays is used to maintain conventional storage batteries in a state of charge. The cathodic protection system is in turn energized from the batteries. It is usual to incorporate sufficient battery storage to accommodate a number of 'no-sun' days. Quite large capacity schemes have been effectively used in north and east Africa. Theft is a problem.

Wind power has been used to a small extent but it is likely, as domestic wind 'microgeneration' becomes more popular for environmental reasons, that such systems will fall in cost and increase in efficiency. Combined PV and wind systems may be optimum solutions in some locations.

#### **4.21.12.3.2 Other power supply systems**

Thermoelectric generators using catalytic converters and direct dc electrical generation with no moving parts, small gas turbine generators, turbines powered by water, oil, or gas flow across a flow constricting valve with a bypass loop, as well as gas and oil fuelled generators have all been used for cathodic protection in remote locations. They remain small scale due to the cost and efficiency advantages of AC power distribution and transformer rectifiers.

### **4.21.13 Conclusion**

Although the principles of cathodic protection are essentially simple and were in fact first outlined by Sir Humphrey Davy in 1824, the application of the method to practical problems was described as more of an art than a science by the authors of the earlier edition of this chapter. In the years that have passed since that edition, the science and calculation procedures have been developed and proven that have, in the view of this author, taken the element of art out of the science and technology of cathodic protection. A properly designed cathodic protection system will be economic and effective and will deliver reliability for its design life. Regrettably, such systems can only be delivered by designers, suppliers, and contractors

with sufficient expertise and experience to warrant certification of competence; there continue to be some cathodic protection systems that do not deliver economic, effective, or reliable solutions to owners or operators who sadly find themselves served by less competent people claiming to be specialists. These schemes can be inefficient and uneconomical and, under certain circumstances, may accelerate corrosion instead of controlling it.

### 4.22.1 The Phenomenon of AC Corrosion

The primary factor in alternating current electrolysis is current density.<sup>1</sup> This statement was made in *The Engineering Journal*, the journal of the Engineering Institute of Canada, and was made in 1927.

A long time has passed since then and AC effects have been experienced and investigated in depth.

More recently, since 1986, some instances of corrosion on gas pipelines due to alternating current (16.6 and 50 Hz) have been reported in Europe and elsewhere.<sup>2–4</sup> In all these cases, the cathodic protection (CP) values, measured with conventional techniques and instruments, satisfied the conventional criteria. It is also most probable that some previous corrosion failures have not been recognized as being caused by alternating current, because CP personnel have not been made aware of the AC corrosion risk.

Very often in the past, AC corrosion was not correctly diagnosed, because usually, CP instrumentation rejects industrial AC frequencies and the knowledge of the AC corrosion phenomenon itself is still growing every day.

In the last decade, quite a number of corrosion instances have been clearly attributed to AC corrosion.

AC corrosion is a concern for owners operating long structures (mostly pipelines) running parallel or close to overhead high-voltage transmission power lines (typically 15 kV and higher) or AC traction systems. The problem also exists in municipal areas (structures buried near AC power distribution systems), in reinforced concrete structures (e.g., road bridges also carrying electricity power lines), and inside tunnels for AC electrified railways.

It is not uncommon to measure AC voltages in the range of 15–100  $V_{rms}$  on coated pipelines exposed to AC influence. This may cause safety hazards to people, malfunction of the pipeline equipment, and corrosion problems.

In the last two decades, a better knowledge of the AC corrosion phenomenon has been gained, thanks to the many studies that mainly gas operators have sponsored or directly performed.<sup>4–6</sup>

These studies started in the 1980s and are still in progress. Since this period, high-quality/high-resistance coatings have been used for buried pipelines, thus increasing the effects of AC interference.

### 4.22.2 Sources of AC Interference

The AC influence is referred to as ‘inductive,’ ‘resistive,’ or ‘capacitive’ interference in technical literature.

The most common long-term AC interfering sources on buried metallic pipelines are

- AC overhead or underground electricity power lines;
- AC traction systems fed by a parallel high-voltage feeding line (50 or 16.6 Hz).

Long-term AC interference on a buried pipeline may cause corrosion because of an exchange of AC current between the exposed metal of the pipeline and the surrounding electrolyte at the coating holidays.

This exchange of current depends on the AC voltage, whose amplitude is related to various parameters such as

- the configuration of AC power line phase conductors and shielding wires;
- the distance and the length of parallel path between the AC power line/traction system and the pipeline;
- the current flowing in the AC power line/traction system phase conductors;
- the average insulating resistance of the pipeline;
- the thickness of the coating; and
- the soil resistivity.

### 4.22.3 Interference Effects

When an AC voltage is present on a cathodically protected pipeline and defects in the coating are present, an AC current will flow across the metal-soil interface. This current depends on the impedance of the system.

During the negative half-wave, the combined AC and DC current will result in the reduction of any reducible species that is in contact with the metal, for example, the formation of hydrogen and hydroxyl ions according to eqn [3]. During the positive half-wave, the current may cause the charging of the double layer capacitance, possible oxidation of hydrogen, and reduced corrosion products due to the CP, and oxidation, that is, corrosion, of the pipeline steel. Since this current leaving the metal surface can be consumed by several noncorrosive processes, generally, voltages higher than 10 V are required to result in a significant corrosion attack to the pipeline steel. Various additional parameters influence this process; among others, the most important ones are the leakage or earth resistance of the defect, the level of CP and the chemical composition of the soil.

- The leakage or earth resistance  $R_L$  is generally due to the geometry of a defect that is in contact with the soil of resistivity ( $\rho$ ). Considering a circular defect with diameter  $d$ , the following formula yields

$$R_L = \rho/2d \quad [1]$$

Equation [1] is useful for a rough estimation of  $R_L$ ; however, it should be considered that the soil resistivity may vary significantly in the vicinity of a coating defect, and both the soil resistance in the defect (considered within the thickness  $s$  of the coating) and the polarization resistance have been neglected.

- CP generally creates electrochemical reducing conditions at the steel surface and results in the formation of hydroxyl-ions according to

and/or

This is combined with an increasing alkalinity (up to pH 11–12 and even more) and a significant decreasing of the resistivity of the soil close to the steel surface.

- From soils containing calcium ( $\text{Ca}^{2+}$  or other alkali earth ions), it is known that insoluble calcareous layers ( $\text{CaCO}_3$ ) are formed on the cathodically protected steel surface. This is due to the highly alkaline conditions and reactions with  $\text{CO}_2$  in the soil. The result is an increasing leakage or earth resistance of the defect. In alkali ion ( $\text{Na}^+$ ,  $\text{K}^+$ )-rich soils, however, similar reactions produce soluble bicarbonates (e.g.,  $\text{NaHCO}_3$ ), thus resulting in a decreasing leakage resistance.<sup>7</sup>

The processes thought to be taking place have been summarized as follows:<sup>8</sup>

During the positive half-wave, the bare metal surface is oxidized, resulting in the formation of a passive film. This is due to the current that leaves the metal surface. During the negative half-wave, when both AC and DC current enter the metal surface, this passive film may be reduced to iron hydroxide. In the following anodic cycle, a new passive film grows. Upon reduction of the passive film, the amount of iron hydroxide is increased. Hence, every AC cycle results in some oxidation of the metal. In the long term, this can result in a significant metal loss.

#### 4.22.4 Calculation of AC-Induced Voltage

An AC voltage that may cause corrosion can result from resistive or inductive interference from high-voltage power lines and/or electrified railways; induction is the most frequent interference mode. The AC voltage  $U_{ac}$  should be calculated in accordance with CIGRE Technical Brochure No. 95 published in 1995 “*Guide on the Influence of High Voltage AC Power Systems on Metallic Pipelines.*”<sup>9</sup>

The evaluation of  $U_{ac}$  is generally based on the calculation of the induced longitudinal field strength  $E$  for a segment of the pipeline.

The field strength  $E$  depends on

- the value and the frequency of the inducing current;
- the mutual inductance – related to the unit length – between the conductor(s) of the high-voltage line and the pipeline, that is, a function of their clearance and of the soil resistivity;
- the reduction factor, allowing for the protective effect of adjacent earthed conductors.

For simplified conditions (e.g., parallel routing between high-voltage line and pipeline, uniform coating resistivity of the pipeline, constant soil resistivity, and both ends of the pipeline being terminated by a low resistance to earth), an analytical solution for  $U_{ac}$  as a function of pipeline length may be evaluated.<sup>9</sup> In practice, however, calculations are generally carried out by using computers, taking into account the relevant parameters of the high-voltage line and the pipeline.

**Figure 1** Typical AC corrosion on a PE-coated pipeline. Reproduced from Corrosion due to AC on metallic buried pipelines: Background and perspectives L. Di Biase APCE, 2nd National Conference, Rome, Nov. 1996; pp 21–22.

These calculations are, among others, based on the following information and documentation:

- drawings showing the right way of the high-voltage lines and the pipeline together with the location of power stations, substations, transformer stations, overhead line towers, and pipeline CP stations;
- the rated voltage and the type of earthing of the high-voltage system;
- nominal or operating and peak (inducing) current of the high-voltage line;
- the configuration of the towers and the conductors;
- the diameter and insulation resistance of the pipeline;
- the location of isolating joints and leakage resistance of any structure that provides grounding of the pipeline; and
- the reduction factor of the high-voltage line and the case being of other reducing conductors.

$U_{ac}$  as a function of pipeline length,  $l$ , is then obtained from the vectorial sum of the induced voltage from each considered individual pipeline segment.

As an example, **Figure 4** shows the results of calculated  $U_{ac}$  for a pipeline, DN 500, laid in 1999. Isolating joints are installed at km 0 and km 62. The pipeline is inductively interfered by four 50 Hz high-voltage lines (110 kV/220 kV); the level of operating currents is between 520 and 960 A. The coating insulation resistance is 1 and 100  $k\Omega m^{-2}$  according to results from CP measurements. By installing two grounding electrodes,  $U_{ac}$  may be kept below the safety threshold for people, even though, to avoid AC corrosion, further measures are still to be adopted.

#### 4.22.5 Evaluation of the AC Interference Effects

On pipelines suffering from AC interference, pipe-to-soil protection potentials satisfying the requirements of the relevant standards do not guarantee efficient protection against corrosion. A specific approach to assess the likelihood of AC corrosion should be adopted.

The AC voltage induced on a pipeline is considered as the most important parameter to be taken into account when evaluating the adverse influences of an AC system.

The factors which mainly influence the AC corrosion phenomena are

- the induced AC voltage;
- the AC current density on the exposed metal;
- DC polarization;
- the size of coating defects;
- the local soil resistivity; and
- the local soil chemical composition.

In order to assess the actual risk of AC corrosion on a pipeline interfered by a high-voltage power line, the following methods can be used:

- Indirect assessment by installing coupons along the right of way of the pipeline where the corrosion risk is expected to be highest. Appropriate locations may be found at pipeline sections where the AC voltage reaches the highest values (see [Figure 4](#)).

These coupons (typically having a bare steel area of  $1 \text{ cm}^2$ ) are bonded with cables to the pipeline, thus allowing to measure the voltage and the current density (DC, AC).

According to EN TS 15280 issued in March, 2006,<sup>6</sup> the following limits apply:

The pipeline is considered protected from AC corrosion if the rms AC current density ( $\mathcal{I}_{ac}$ ) on the coupon is less than  $30 \text{ A m}^{-2}$ .

In practice, the evaluation of AC corrosion likelihood on a broader base can be made as follows:

- $\mathcal{I}_{ac}$  lower than  $30 \text{ A m}^{-2}$ : no or low likelihood;
- $\mathcal{I}_{ac}$  between  $30 \text{ A m}^{-2}$  and  $100 \text{ A m}^{-2}$ : medium likelihood;
- $\mathcal{I}_{ac}$  higher than  $100 \text{ A m}^{-2}$ : very high likelihood.

If electrical resistance (ER) coupons are used, the corrosion rate can be measured instantly. The coupon sensitivity should be carefully chosen in such a way that corrosion rates in the order of  $0.01 \text{ mm year}^{-1}$  can be measured with sufficient accuracy over a period of some months.

- Indirect assessment by measuring the AC voltage along the pipeline and correlating the results with the actual operating conditions of the interfering high-voltage system.

According to EN TS 15280 issued in March, 2006,<sup>6</sup> the following limits apply:

To reduce the AC corrosion likelihood on a buried pipeline, the pipeline AC voltage, measured at selected test points, should not exceed at any time:

- 10 V at which the local soil resistivity is greater than  $25 \Omega \text{ m}^{-1}$ ,
- 4 V at which the local soil resistivity is less than  $25 \Omega \text{ m}^{-1}$ .

These values should be considered as threshold limits, which significantly reduce the AC corrosion likelihood; they are based on a long-term practical experience of many European pipeline operators.

- Direct assessment by performing potential gradient measurements along the pipeline, followed by excavation of sites where results indicate small defects in the coating. In case of pipelines that can be inspected with an intelligent pig and after a sufficient duration of the interference (e.g., 2 or more years), the loss of wall thickness may also be detected by ultrasonic or magnetic flux leakage intelligent pigs.

#### 4.22.6 Mitigation of AC Interference Effects

In order to reduce the AC corrosion risk of an existing pipeline, generally, the AC voltage between pipeline and soil and the level of the CP system can be modified and adjusted by the operator.

The AC current density in a defect of the pipeline coating is directly proportional to the AC voltage, thus any reduction of the voltage reduces the likelihood of AC corrosion.

The following **Table 1** summarizes some possible mitigating measures and shows advantages and the associated, possible drawbacks:

- The level of the CP should also be considered. Some laboratory tests have shown<sup>8</sup> that excessive DC current densities (e.g., exceeding  $5 \text{ A m}^{-2}$ , measured on bare coupons) may increase the AC corrosion rate, due to the accumulation of hydroxyl-ions close to the metal–soil interface. The subsequent reduction of the leakage resistance at the defect may lead to increasing AC and DC

current densities and an increased likelihood to reduce the passive film that is formed during the anodic half-wave of the AC current.<sup>10,11</sup>

According to the aforementioned reactions, in order to further reduce the likelihood of AC corrosion, besides the reduction of the AC voltage on a pipeline, its On-potentials (which are the driving force for the CP current) should not be much more negative than the ones needed to satisfy the CP Off-potential criterion of the pipeline.<sup>11</sup>

However, in case of DC-interfered pipelines with high-quality coatings (which are more prone to AC corrosion), it is difficult to practically cope with the reduction of the On-potential and the simultaneous control of the DC corrosion risk.

#### 4.22.7 Major Evidence from Field Studies and Laboratory Tests

1. AC corrosion is more likely to happen on buried pipelines coated with high-resistance coatings (e.g., three-layer polyethylene) than on pipelines with older bituminous coating types (even though some case histories have been reported where AC corrosion also happened on pipelines coated with bituminous coatings).
2. AC corrosion usually appears in the area along the pipeline that is highest interfered.
3. AC corrosion likelihood could further be reduced by carefully adjusting the On-potential of pipelines to values no more negative than the ones needed to satisfy CP Off-potential criteria

**Table 1** Summary of measures to reduce the AC voltage on interfered pipelines

Mitigation measure	Advantages	Possible drawbacks
Increasing the distance between pipe and high-voltage line/electrified railway	–	<ul style="list-style-type: none"> <li>• Very efficient solution but only possible for new designed pipes or interfering systems</li> <li>• Not possible for existing systems</li> </ul>
Arrangement of phase and earth wires of high-voltage line	–	<ul style="list-style-type: none"> <li>• Only possible for new designed high voltage power lines</li> <li>• The solution only depends on the electricity company</li> </ul>
Earthing of pipeline through AC discharge devices	<ul style="list-style-type: none"> <li>• Generally good technical solution and cost efficient</li> </ul>	<ul style="list-style-type: none"> <li>• Problems may occur in high resistivity soil due to high resistance of groundings</li> </ul>
Compensation of AC voltage	–	<ul style="list-style-type: none"> <li>• Difficult to settle</li> <li>• High cost of installation and operation</li> </ul>
Installation of isolating joints	<ul style="list-style-type: none"> <li>• Good possibility to vary an optimum configuration by calculation and design</li> </ul>	<ul style="list-style-type: none"> <li>• Installation of joints involves direct interference with pipeline operation</li> </ul>
Earthing of pipeline by using earthing wires	–	<ul style="list-style-type: none"> <li>• High cost and poor efficiency</li> </ul>

(e.g., EN 12954).<sup>12</sup> Nevertheless, this mitigation measure is to be considered quite difficult in its practical application and sometimes (e.g., presence of DC interference) not possible.

### 4.23.1 Introduction and Historical Background

#### 4.23.1.1 Voltage, Current, and Resistance Measurement

This chapter is essentially a review of former methods for electrical measurement. Although a description of these older instruments and methods is now of historical interest, it presents a valuable understanding of the principles of measurement, which are obscured when considered in conjunction with modern digital instruments.

Historically, nearly all DC electrical measuring instruments were of the moving-coil permanent-magnet type, which gave a coil deflection (and thus pointer deflection) proportional to the current in the coil. The damping of the movement to prevent over swing or the oscillation of the needle is provided by the eddy currents induced in the metal former on which the coil is wound, and further damping (i.e., critical damping) can be obtained by placing a low resistance across the coil. The main advantages of

this type of instrument are uniformity of scale, high torque–weight ratio, and low power consumption. By the insertion of suitable shunts and/or resistances, it is possible to use one instrument to measure both current and voltage over a wide range.

It is often not appreciated that modern digital multimeters (DMMs) function in exactly the same way as traditional instruments except that the moving coil meter is replaced by an electronic operational amplifier and that the display is digital rather than analog. The main measurement advantage of a DMM is their considerably higher input impedance as voltmeters. They also have a number of obvious technical advantages, such as robustness, ease of use, etc.

#### 4.23.1.2 Voltmeters and Potentiometers

The current flowing through any potential-measurement circuit must be as small as possible to avoid errors due to polarization of the voltage source. Moreover, if the current flow is too large, errors will be introduced owing to the voltage drop caused by the contact resistance between the reference electrode and the electrolyte. It is thus clear that the prime requirement of an accurate potential measurement circuit is high resistance. For direct-reading instruments, the input impedances were typically as low as  $50\,000\,\Omega\,V^{-1}$ , and instruments were commercially available with input impedances of  $\sim 1\,M\Omega\,V^{-1}$ . Direct-reading meters were usually made to show several ranges, which are obtained by the use of suitable resistances placed in series with the indicating instrument (Figure 1).

For digital instruments, the input impedance is dependant upon the characteristics of the input amplifier used; instruments are available in three bands of performance:  $10\text{--}20\,M\Omega$  for inexpensive, robust devices;  $1\,G\Omega$  for more specialist equipment; and  $>10^{14}\,\Omega$  for electrometer type instruments. This avoids significant polarization of reference electrodes and measurements of accurate steel/electrolyte/electrode potentials in high resistivity electrolytes in soils and concretes. However, it is still important to understand the principles involved.

To measure structure/electrolyte/electrode potentials in electrolyte resistivities in excess of  $20\,\Omega\,m$ , bridge ‘backing off’ potentiometer instruments as shown in Figure 2 or potentiometric voltmeters as

**Figure 1** Direct reading voltmeter.

**Figure 2** Potentiometer voltmeter (courtesy of The Post Office).

illustrated in **Figure 3** were traditionally used until the advent of high-impedance digital technology.

In both types of instrument, the voltage to be measured is balanced against an external applied voltage (usually from batteries within the instrument). At balance, no current flows through the external circuit and thus errors due to contact resistance and source impedance are eliminated.

The potentiometer requires to be calibrated against a standard cell, while with the potentiometric voltmeter, the voltage to be measured is balanced against a battery emf, using uncalibrated resistors and the voltmeter as a galvanometer. At balance, the voltage is transferred to the voltmeter and read directly. The magnitude of voltage that can be measured by both instruments is limited by the maximum voltage of the (usually) dry cell they contain. It is, however, possible to extend the range by using a potential divider or volt box. For normal field work, the potentiometric voltmeter was the more popular instrument, being usually of lighter construction and not requiring calibration against a standard cell. Where extremely small potentials (usually potential shifts) of the order of 1 mV were to be measured, however, the potentiometer was more suitable and accurate.

The technique adopted in measuring structure/electrolyte potential is illustrated in **Figure 4**. It should be noted that the position of the reference electrode in relation to the structure is important. Theoretically the half-cell should be placed as near to the structure as possible (i.e., within a few millimeters) to avoid  $IR$  (ohmic) drop in the electrolyte. This is often not possible in practice as, for example, with a buried pipeline. In such a case, the cell should be placed in the soil directly over the structure, and it is accepted good practice, historically, to allow a 'safety factor' of say 50 mV over and above the minimum protective potential to compensate for  $IR$  drop.

These  $IR$  drop errors are now (and have been since the 1950s in continental Europe) minimized

by the measurement of Instant OFF potentials, typically within a period of 0.1–1 s after interrupting the cathodic protection current. There remains (in 2009) a debate in the US pipeline industry regarding the need for such 'sophistication' in measurement and whether there is a need to increase the level of polarization to pipelines to accommodate the previously unknown  $IR$  drop errors, in particular for pipelines where existing levels of polarization have historically controlled corrosion to adequate levels. The key issue appears to be that the magnitude of the  $IR$  error will vary with soil resistivity, coating quality/defect size, the quality of polarization films on the steel surface and may be as much as several hundreds of millivolts; without the 'sophistication' of Instant OFF potential measurements, there can be no reliance on the accuracy of potential measurements. This concept is well accepted in most of the world.

#### 4.23.1.3 Current-Measuring Instruments (Ammeters)

These may be classified generally according to whether they are used to measure current delivered or drained by a structure receiving cathodic protection or to measure current flowing within the structure itself.

By the use of suitable shunts, the basic moving-coil movement (and the DMM) can be adapted to measure an almost unlimited range of currents. **Figure 5** illustrates a direct-indicating instrument with shunt to

**Figure 3** Basic circuit potentiometer voltmeter.

**Figure 4** Measurement of structure/electrolyte potential.

measure current up to 5 A DC. To ensure that the resistance of the circuit is not materially altered by the insertion of an ammeter, it is usual to install either a shunt or the meter itself (usually a moving-coil meter with internal shunt) permanently in the circuit. Ammeter shunts are normally of the four-terminal type to avoid contact resistance errors, that is, two current terminals and two potential terminals.

Importantly, in making measurements of current flowing within a structure, it is extremely important that additional resistance, for example, an ammeter shunt, is not introduced into the circuit, as otherwise erroneous results will be obtained. One method is to use a tong test meter. Such instruments are, however, not particularly accurate, especially at low currents, and are obviously impracticable in the case of, say, a 750-mm diameter pipeline. A far more accurate method and one that can be applied to all structures is the zero-resistance ammeter or, as it is sometimes called, the zero-current ammeter method. The basic circuit of such an instrument is shown in **Figure 6**.

From **Figure 6**, it will be seen that if  $I_b$  is adjusted until there is zero voltage on the voltmeter, then  $I_s = I_b$ . When this type of instrument is used to measure current in, say, a bond between one structure

**Figure 5** Direct-indicating current measuring instrument (ammeter).

**Figure 6** Zero-resistance ammeter.

and another, if simultaneous measurements are made at locations on the structure (i.e., interference testing) inaccurate results will be obtained, because at balance there is no current in the structure at the measurement point, and this could materially alter the current distribution to the structure.

The zero-resistance ammeter is seldom employed for routine testing; however, the above circuit can be used utilizing modern digital instruments and a current source to 'back off' the current flowing in the structure and measure this current in the external ammeter/shunt. As already noted, a DMM measures current in precisely the same manner as a moving coil instrument. Thus, the modern use of a DMM does not negate an understanding of how current shunts function in practice.

#### 4.23.1.4 Measurement of Resistivity/Conductivity

The most usual method of measuring soil resistivity is by the four-electrode 'Wenner' method. **Figure 7** indicates the basic circuit. The mean resistivity  $R_m$  is given by

$$R_m = 2a(E/I)$$

where  $I$  is the current applied between the current electrodes  $C_1$  and  $C_2$  and  $E$  is the potential developed between the potential electrodes  $P_1$  and  $P_2$  by the current  $I^*$ . The value given by this method is the average resistivity of the soil to a depth equal to the spacing of the electrodes. The average is weighted to the surface material as the 'sampled' volume is actually a hemisphere below the two center pins  $P_1$  and  $P_2$  in **Figure 8**. There is a simple calculation technique whereby measurements taken at the same general location but at different pin spacings/depths can be expressed as the resistivity of the individual layers from the surface to the maximum depth measured. This analysis is extremely useful in assessing the likely corrosivity at pipeline depth and is essential as a precursor to the design calculation of groundbed resistance/optimum dimensions.

It is most important to note that for accurate and consistent results, the electrodes must be equidistant from one another and placed in a straight line. The relatively simple setup, illustrated in **Figure 7**, suffers from inaccuracies arising from the polarization of the potential electrodes and effects of possible stray currents in the soil.

To avoid the errors of polarization and stray currents, four-pin earth resistivity meters are employed.

(a) 'Wenner' 4 pin method:  $C_1$ ,  $C_2$  and  $P_1$ ,  $P_2$  are steel rods driven into the soil. Modern devices use an AC source thus avoiding errors due to polarisation of the pins and standing field gradients between  $P_1$  and  $P_2$

(b) 4 Pin Earth Resistivity Meter using a hand cranked AC generator. More modern devices use battery/electronic AC circuits but this device remains one of the most sensitive

**Figure 7** 'Wenner' 4 pin earth resistivity determination.

These use an alternating current produced from battery-powered electronic, or in older equipment, a hand-generated current passed through the current coil of an ohmmeter and then through a current reverser so that an alternating current is delivered. The effective resistance is measured by a modified Wheatstone bridge with balance indicated by a galvanometer, **Figure 8**.

The resistivity of an electrolyte can also be measured by passing a known current through a known length and cross section of the electrolyte and measuring accurately the voltage drop across the length. It is normal to use alternating current in order to avoid polarization effects. Special cells also exist for use with resistivity meters, which are so constructed and calibrated that resistivity can either be read directly from the instrument or simply calculated from the product of the measured resistance and known cell constant. Measurements of resistivity on samples will give accurate results only on liquid electrolytes and are also used commonly for the measurement of selected soil or saline mud samples, but caution should be exercised as the value of resistivity measured will vary with the degree of compaction of the soil. The measurement of electrolyte conductivity, the reciprocal of the resistivity, is

**Figure 8** 'Megger' earth resistivity meter (courtesy Evershed and Vignoles).

calculated from the resistivity as measured by some of the methods described earlier.

Often it is necessary in designing a cathodic-protection system to know the conductivity of a protective coating (coating conductance) on a structure. This measurement may be carried out in an

approximate manner by finding the resistance between an electrode of known area placed in contact with the coating and the structure itself. The electrode placed on the structure can be either of thin metal foil or, preferably, of material such as flannel soaked in weak acidic solution. The resistance between the pad and the metal is measured by means of a resistivity meter, as previously described. More accurate data on coating conductance can be calculated, postconstruction and after commissioning the cathodic protection system, using the classic attenuation formulae and measured pipe/soil potential shifts along the pipeline. In some pipeline construction contracts, such measurements are used as a quality management tool and failure to comply with a maximum coating conductance will result in remedial works being required.

#### 4.23.1.5 Measurement of Resistance/Conductance

As previously mentioned, four-pin earth resistivity meters can be used to measure resistances. Modern DMMs are also able to measure resistance. The measurement of resistance to the remote earth of a metallic structure is normally carried out with a four-electrode instrument. The connections are shown in **Figure 9**. A current is passed between the structure and a remote electrode and the potential difference measured between the structure and a second remote electrode. In this way, the ohmmeter records the resistance of the structure to earth, that is,  $V/I$ . The spacing of the electrode from the structure is important and must be such that the remote potential electrode lies on the horizontal part of the resistance–distance curve, as shown in **Figure 9**. Generally speaking, a minimum

distance of 15 m from the structure is necessary for the potential electrode to lie on the flat part of the curve, with the current electrode usually at least twice the distance of the potential electrode.

### 4.23.2 Basic Requirements for Routine Testing Instruments

#### 4.23.2.1 Digital Instrumentation

All instruments used in cathodic protection work must be sufficiently rugged for field use with appropriate ranges, resolution, and accuracy. They should be externally, formally, calibrated and calibration records and copies of the certificates should be available to the engineers or technicians using them so that they can be certain that the instruments they use are within calibration.

Most cathodic protection measurements comprise DC voltage/potential values, along with resistance and DC currents, either low current directly via shunts within the meter or using external high-current shunts, plus a range of AC measurements (subject to appropriate training and certification of personnel to work on mains voltage equipment). Thus, a wide range of conventional electrical test multimeters are extensively used. For general field applications, suitable instruments are available that are water resistant to BS EN 60529 IP 64 dust-tight and splash resistant or IP 67 dust-tight and resistant to immersion; explosion hazard certificated equipment is available for use in hazardous areas. Some typical high-quality digital instruments are shown in **Figure 10** and will have characteristics generally similar to those listed in **Table 1**.

These devices comprise a microcomputer, a data acquisition device, and an analog-to-digital converter along with a digital display, selector switches, fuses, shunts, battery, and terminals. The instruments include self-test and internal calibration checks; DC voltage measurements take typically 0.5–1 s to complete and replenish on the display, whereas AC voltage measurements may take considerably longer and resistance measurements generally take longer than DC measurements and less than AC measurements.

For the important DC voltage measurements used in performance assessment of cathodic protection systems, the input impedance is important, particularly for measurements in high-resistivity soils and concretes. Typical input impedance values for the normal 2 V DC range will be 10 or 20 M $\Omega$ , which

**Figure 9** Measurement of resistance of structure to remote earth.

**Figure 10** Typical digital multimeters (DMMs) used in cathodic protection measurements.

**Table 1** Typical characteristics of a DMM

Voltage range		Resolution		Accuracy, $\pm\%$ of reading + no. of digits	
DC	AC	DC	AC	DC	AC: 45–1000 Hz
200 mV	200 mV	0.01 mV	0.01 mV	0.04% + 2	0.2% + 10
2 V	2 V	0.1 mV	0.1 mV	0.04% + 2	0.5% + 10
20 V	20 V	1 mV	1 mV	0.05% + 2	0.5% + 10
200 V	200 V	10 mV	10 mV	0.05% + 2	0.5% + 10
1000 V	750 V	100 mV	100 mV	0.05% + 2	1% + 10
Current range		Resolution		Accuracy, $\pm\%$ of reading + no. of digits	
DC	AC	DC	AC	DC	AC: 45–1000 Hz
200 $\mu$ A	200 $\mu$ V	0.01 $\mu$ V	0.01 $\mu$ V	0.02% + 2	0.75% + 10
2 mA	2 mV	0.1 $\mu$ V	0.1 $\mu$ V	0.02% + 2	0.75% + 10
20 mA	20 mV	1 $\mu$ V	1 $\mu$ V	0.03% + 2	0.75% + 10
200 mA	200 mV	10 $\mu$ V	10 $\mu$ V	0.03% + 2	0.75% + 10
2 A	2 A	100 $\mu$ V	100 $\mu$ V	0.03% + 2	1% + 10
Resistance range		Resolution		Accuracy, $\pm\%$ of reading + no. of digits	
DC	AC	DC	AC	DC	AC: 45–1000 Hz
200 $\Omega$	200 $\Omega$	0.01 $\Omega$	0.01 $\Omega$	0.07% + 4	0.07% + 2
2 k $\Omega$	2 k $\Omega$	0.1 $\Omega$	0.1 $\Omega$	0.07% + 2	0.07% + 2
20 k $\Omega$	20 k $\Omega$	1 $\Omega$	1 $\Omega$	0.07% + 2	0.07% + 2
200 k $\Omega$		10 $\Omega$		0.07% + 2	
2 M $\Omega$		100 $\Omega$		0.15% + 2	
2 M $\Omega$		10 k $\Omega$		0.2% + 2	
20–100 M $\Omega$		100 k $\Omega$		1% + 3	
100–300 M $\Omega$		1 M $\Omega$		2% + 3	

will be insufficient for accurate measurements with normal reference electrodes in soils and concretes of  $\sim > 500 \Omega \text{ m}$ . Very few instruments are available with a switchable input impedance; one favored for use in reinforced concrete applications is switchable between 10 and  $> 10\,000 \text{ M}\Omega$ .

Noise rejection, the avoidance of error in the DC measurement due to AC, which may be superimposed on the structure being measured (typically but not exclusively a pipeline) or may be collected (typically by induction) into the test cables used in the measurements, is also important in measurements of cathodic protection DC voltage, particularly with high-impedance instruments where very low currents flow in the measurement circuits. Good quality instruments will have high levels of noise rejection with typical good values being  $> 60 \text{ dB}$  at 50–60 Hz normal mode noise rejection and  $> 120 \text{ dB}$  common mode noise rejection at DC and  $> 90 \text{ dB}$  at 50–60 Hz.

With the ability to deploy to site such extremely versatile and accurate multifunction digital test equipment, cathodic protection personnel should also use, some on a daily basis or at the start and end of a ‘campaign’ of measurements, a portable calibration device or a second instrument such that the accuracy of the instrument used for measurements in the field can be confirmed.

#### 4.23.2.2 Measurement Errors

It is all too easy to be ‘fooled’ by an instrument into assuming that the number presented on its display, or recorded for later analysis, is somehow ‘accurate.’ This is completely untrue. The terms sensitivity, accuracy, and precision have precise definitions and it is important for operators to understand what they mean.

Sensitivity is the smallest possible signal that an instrument can measure, accuracy is the degree to which the measurement is close to the actual (true) measurement, while precision is the degree to which further measurements will show the same or similar results (also called reproducibility).

A single measurement or a series of measurements may be accurate (but not precise), precise (but not accurate), both of these, or neither. These differences essentially relate to errors in measurement, which may be random or systematic. Random error relates to unquantifiable differences in how a measurement is undertaken; systematic error is an always-present offset from the true value. This difference is illustrated in [Figure 11](#).

**Figure 11** Random and systematic errors.

#### 4.23.3 Reference Electrodes

The generally accepted criteria for the effectiveness of a cathodic protection system are all related to the structure/electrolyte potential. The protection criteria for carbon (mild) steel in various electrolytes are summarized in [Table 2](#).

Note: Aluminum alloys have protection criteria similar to those for steel. Higher strength steels, aluminum, high-strength copper–nickel alloys, and coated steels have negative potential limits to avoid hydrogen embrittlement and coating disbondment or, in the case of aluminum, amphoteric corrosion. Elevated temperatures require more negative protection criteria. Stainless steels have less negative protection criteria and duplex stainless steels may be subject to hydrogen embrittlement. Steel in concrete has a potential limit of  $-1100 \text{ mV}$  for reinforcing steel and  $-900 \text{ mV}$  for prestressing steel both referred to  $\text{Ag}/\text{AgCl}/0.5 \text{ M KCl}$ .

In order to measure the metal/electrolyte potential, it is necessary to make a metallic contact to the metallic structure itself and an electrolytic contact with the electrolyte (soil, water, or concrete). The problem of connection to the structure normally presents no significant difficulties except in respect of access; for example, in the case of concrete, the steel needs to be exposed for connection and the electrical continuity between the bars needs to be established. However, contact with the electrolyte must be made with a reference electrode that presents a stable interface or half-cell potential with the electrolyte under all conditions. (If e.g., an ordinary steel probe were used as a reference electrode, then inaccuracies would result for two main reasons: first, electrochemical action between the probe and the soil, and second, polarization of the probe owing to current flow

**Table 2** Cathodic protection criteria for carbon steel in various environments

<i>Electrolyte</i>	<i>Prime criteria</i>	<i>Alternative criteria</i>	<i>Alternative criteria for consideration</i>	<i>Prime standards</i>
Aerobic soils, insignificant microbial activity (notably sulfate reducing bacteria SRBs)	More negative than –850 mV referred to Cu/CuSO <sub>4</sub> (sat.) polarized potentials (instant OFF)	100 mV decay or polarization (measured instant OFF)	More negative than: –750 mV for 100 < $\rho$ < 1000–650 mV for $\rho$ < 1000 $\Omega$ m	ISO 15589–1: As revised for BS EN 14919–1. BS EN 12954 (not 100 mV decay/shift)
Anaerobic soils with significant microbial activity (notably sulfate reducing bacteria SRBs)	More negative than –950 mV referred to Cu/CuSO <sub>4</sub> (sat.) polarized potentials (instant OFF)	N/A	N/A	ISO 15589–1 As revised for BS EN 14919–1. BS EN 12954
Aerobic Waters, insignificant microbial activity (notably SRBs)	More negative than –800 mV referred to Ag/AgCl/sea water (equivalent to –850 mV referred to Cu/CuSO <sub>4</sub> (sat.) Polarized potentials Instant OFF)	N/A	N/A	BS EN 12473
Anaerobic waters (e.g., under decaying marine growth as in accelerated low water corrosion (ALWC) with significant microbial activity (notably SRBs)	More negative than –900 mV referred to Ag/AgCl/sea water (equivalent to –950 mV referred to Cu/CuSO <sub>4</sub> (sat.) polarized potentials instant OFF)	N/A	N/A	BS EN 12473 CIRIA C 634 management of ALWC in steel marine structures
Concrete	Potential decay from instant OFF of: At least 100 mV during 24 h Or At least 150 mV during a period > 24 h	More negative than –720 mV referred to Ag/AgCl/0.5 M KCl (equivalent to –720 mV referred to Ag/AgCl/sea water) (instant OFF)	Fully depolarized or unprotected steel in concrete less negative than –150 mV referred to Ag/AgCl/0.5 M KCl (passive within protective concrete)	BS EN 12696

through the measuring circuit.) Reference electrodes are metal electrodes immersed in a solution of one of its salts; in the simplest form the copper/copper sulfate (saturated) reference electrode, Cu/CuSO<sub>4</sub> (sat.), comprises a pure copper electrode immersed in a saturated solution of CuSO<sub>4</sub>.

The silver/silver chloride electrode range is of a second type where the metal electrode is coated with a salt of that metal and then immersed in a solution of the salt. Thus, there are many types of silver/silver chloride electrodes, with a range of electrode potentials; calling an electrode a silver/silver chloride electrode or Ag/AgCl is an incomplete description and can lead to confusion. Two types of these electrodes are commonly used in cathodic protection. These are the Ag/AgCl/sea water electrode the potential of

which is ONLY stable in sea water of 3.5 wt% salinity. The potential changes with salinity and thus these electrodes should only be used in open sea water. The second is the Ag/AgCl/KCl electrode where the concentration of the potassium chloride will determine the electrode potential. For convenience, the Ag/AgCl/0.5 M KCl, which has an electrode potential within a few millivolts of the Ag/AgCl/sea water (in 3.5 wt% salinity), is widely used but other concentrations are also available. These electrodes are widely used in steel in concrete applications, both as portable survey electrodes and as electrodes permanently cast into concrete, but they should also be used in estuarine waters and can be used as permanent buried electrodes in saline soils. The KCl concentration is maintained in a fixed, stable, condition as is

necessary for long-term electrode potential stability by using a very impermeable porous plug and a gel agent in the solution. The Ag/AgCl/KCl electrode is probably the best reference electrode for measuring potentials of waters at elevated temperatures.

All reference electrodes are subject to small variations in potential due to temperature. For example, the Cu/CuSO<sub>4</sub> (sat.) electrode potential changes at  $\sim 0.9 \text{ mV}/^\circ\text{C}$  so that a pipe/soil potential measurement recording  $-900 \text{ mV}$  Cu/CuSO<sub>4</sub> (sat.) on a hot day ( $30^\circ\text{C}$ ) will, at  $5^\circ\text{C}$ , be measured as  $-878 \text{ mV}$  Cu/CuSO<sub>4</sub> (sat.). Electrode potential changes also occur when the Cu electrode/electrolyte interface is exposed to sunlight; although these effects are reportedly measured to be as much as  $50 \text{ mV}$  more negative in sunlight, they appear to reduce with repeated exposure and are generally accepted to be limited to  $10 \text{ mV}$ . It is good practice to cover the transparent housing of these electrodes when used outdoors. To avoid errors due to polarization effects, it is necessary to restrict the current density on the copper rod to a value not exceeding  $20 \text{ mA cm}^{-2}$ ; this is not an issue with modern digital instrumentation.

The Cu/CuSO<sub>4</sub> (sat.) electrode is vulnerable to electrode potential changes due to chloride contamination; it should not be used in chloride-rich environments such as sea water, estuarine muds, and similar. These electrodes have been unfortunately used in the portable surveys of steel/concrete potential in reinforced concrete structures such as highway bridges, largely because the ASTM Test Method (C876) unwisely specified its use. If, as is the case with most Cu/CuSO<sub>4</sub> (sat.) electrodes, there is contamination of the wooden or ceramic porous plug with copper sulfate, there is a likelihood that there will be significant errors in measurements that may reach  $120 \text{ mV}$ . This is due to a concentration gradient effect known as ‘streaming potentials’ as the concrete is contaminated with copper sulfate. As this error cannot be detected or quantified, it is poor practice to use Cu/CuSO<sub>4</sub> (sat.) electrodes in surveys of steel in concrete.

Another electrode used in sea water and often wrongly called a reference electrode is the zinc electrode. Commonly, both 99.99% pure zinc and the US Mil Spec 18001 anode grade ( $\sim 99.3\%$  pure with small additions of Cd and Al to avoid passivation) are used as electrodes for potential measurement. Neither is accurate and surface condition can result in significant changes in electrode potential; they are however rugged and reliable if inaccurate. If these electrodes are used for permanent installation (they are not normally used for survey purposes except for approximate

potential measurements in oil-contaminated ballast water tanks where the electrode can be introduced through a ‘crust’ of oil and still operate with reasonable accuracy), it is good practice to draw a small current from the electrodes during nonmeasurement periods or if used for potential sensing and control, so that the consumption of the zinc will keep the surface clean and active.

All reference electrode potentials are related to each other. Thus, if the potential of the structure is found to be  $+200 \text{ mV}$  versus Zn, it will be  $-900 \text{ mV}$  versus Cu/CuSO<sub>4</sub> (sat.), and  $-850 \text{ mV}$  versus Ag/AgCl/(sat.) KCl. Approximate values of the these reference electrodes on the standard hydrogen scale (SHE) are as follows: Cu/CuSO<sub>4</sub> (sat.) =  $0.30\text{--}0.32 \text{ V}$ ; Ag/AgCl (sat.) KCl =  $0.020 \text{ V}$  ( $0.025 \text{ V}$  in sea-water); Zn/sea-water =  $-0.75 \text{ V}$ ; this is shown in [Table 3](#). A historic (Admiralty pattern) electrode is shown schematically in [Figure 12](#), while examples of current reference electrodes are illustrated in [Figure 13](#).

## 4.23.4 Other Equipment

### 4.23.4.1 Recording Instruments

Miniaturization of electronic components has enabled the construction of compact, portable, battery-operated recording voltmeters. The principal use of these instruments is to measure pipe/soil potential fluctuations over a period of time, in particular for monitoring the effects of stray traction currents on pipelines. The instruments can be utilized with shunts to measure current variations.

Modern units are now sufficiently small such that they may be mounted into conventional pipeline pipe/soil potential measurement test posts. They can communicate via satellite or global positioning system (GPS) networks and can operate for many months without battery change, for example, as shown in [Figure 14](#). Such units are now becoming of sufficiently low cost to enable operators to consider using them to replace routine pipe/soil potential measurements by technician staff.

### 4.23.4.2 Ancillary Instruments

Apart from the instruments described in previous paragraphs, there are others that, while not directly connected with cathodic protection as such, are extremely useful tools to a corrosion engineer. They include pH meters, Redox probes, protective-coating test instruments, and buried-metal-location instruments.

**Table 3** Approximate comparison of potentials (V) using Zn/seawater electrodes, Cu/CuSO<sub>4</sub> (sat.), and Ag/AgCl, saturated KCl reference electrodes

Silver/silver chloride/ saturated potassium chloride	-1.3	-1.2	-1.0	-0.8	-0.6	-0.4	-0.2	0
Silver/silver chloride/ seawater	-1.4	-1.2	-1.0	-0.8	-0.6	-0.4	-0.2	0

**Figure 13** Typical reference electrodes used in cathodic protection surveys.

#### 4.23.4.2.1 High-voltage coating-testing equipment

When cathodic protection is applied to a structure that has a protective coating, the current required is proportional to the bare metal area on the structure. Thus, whenever a protective coating is applied, it should be of good quality, with very few failures or pin holes in it, so that the cathodic protection system may be economical.

It is standard practice, particularly in the case of pipelines, to carry out an inspection of the protective coating (after application) with a high-voltage tester, known as a holiday detector. Basically, a high voltage is applied between an electrode placed on the coating and the structure. At any 'holidays' (flaws) in the coating, a 'spark-over' occurs and is usually

accompanied by a visual or audible alarm. For pipelines, the electrode often takes the form of a rolling spring clipped round the pipe. Other electrodes are in the form of wire brushes. The high voltage is obtained from batteries and electronic circuitry with a high-tension coil. Such an instrument is illustrated in [Figure 15](#).

For the examination of paint films or special coatings, for example, pipe linings, low-voltage holiday detectors with wet sponge electrodes are available. The choice of voltage for use with a holiday detector depends on the thickness and type of coating applied to the structure. As a guide, in the case of pipelines, a voltage equivalent to  $\sim 5 \text{ kV mm}^{-1}$  thickness is used in testing a thick-film enamel coating.

#### **4.23.4.2.2 Buried metal locating and attenuation measuring instruments**

Instruments in this category are used to locate buried metallic structures, to detect possible electrical discontinuities in buried structures, to locate possible junctions or points of contact between one structure and another, and to indicate the condition of a protective coating applied to a buried structure. A signal of a given frequency is either injected or induced into the structure and traced with a search coil and earphones. Most instruments use a high-frequency signal of 1 kHz or higher, although one or two use a simple interrupter.

Buried pipeline coating survey instruments are available, which, by measurement of the electromagnetic field radiating from a pipeline created by an applied AC signal, are able to compute the attenuation of the signal in dB/km and hence provide an assessment of pipeline coating quality. The signal generator typically operates at a frequency of  $\sim 1$  kHz for thick coatings being selected to minimize interference from commonly occurring frequencies while maximizing the distance the signal will travel, some 5–10 km on a reasonably well-coated pipeline. For thin-film coatings, such as a fusion-bonded epoxy, a frequency of 200 Hz has been found more appropriate.

### **4.23.5 Field Data Loggers and Survey Equipment**

#### **4.23.5.1 Monitoring and Surveys**

It is necessary to understand the difference between monitoring cathodic protection performance and surveying cathodic protection performance. Monitoring is undertaken routinely at fixed points.

For example, on a pipeline, monitoring will be of cathodic protection current and voltage at impressed current transformer rectifiers or at galvanic (sacrificial) anodes and at test points at some 1–2 km spacing along the pipeline at which there will be connections to the pipeline and where there may be buried permanent reference electrodes and or coupons. Coupons may comprise steel elements, possibly of different dimensions ( $5\text{--}25\text{ cm}^2$  are typical), that are normally connected to the pipeline and are used to measure instant OFF potentials without interrupting the cathodic protection current to the pipeline and which are increasingly used to monitor AC current collection/discharge from the pipeline. At these test points, portable  $\text{Cu}/\text{CuSO}_4$  (sat.) reference electrodes will be used in conjunction with the other

facilities to measure pipe/soil/electrode potentials at these fixed locations. These data may be plotted to assess time-dependent changes.

Cathodic protection monitoring on an offshore oil/gas drilling/production jacket with a galvanic anode cathodic protection system will typically comprise permanent  $\text{Ag}/\text{AgCl}$ /seawater reference electrodes, sometimes paired with  $\text{Zn}$ /seawater electrodes, at representative locations at different depths. The measured steel/seawater/electrode potentials may be carried back to measurement and data logging facilities in hard-wired cabling provisions or by acoustic transponders. These facilities enable time-dependent changes in the cathodic protection performance to be assessed, in particular during periods of storm conditions when divers and remotely operated vehicles cannot be deployed to collect survey data.

Cathodic protection monitoring on impressed current cathodic protection systems for steel in concrete will typically incorporate remote data logging of all individual cathodic protection zone transformer rectifier current and voltage outputs and steel/concrete/reference electrode and potential decay probe or pseudo reference electrode ON and instant OFF potential data and potential decay data collected over periods of typically 24 h and often  $> 72$  h from multiple permanent monitoring facilities embedded in the structure. These data will typically be collected every 3 months and plotted/trend analyzed to produce performance verification reports and system review reports.

For all of these applications (but less commonly on steel in concrete applications, as they are typically provided with many fixed monitoring points and surveying of long-term potential decay data can be difficult), in addition to these fixed point monitoring data sets regular steel/electrolyte/electrode potential surveys are undertaken to measure the adequacy of the cathodic protection performance over all or selected parts of the structure between the fixed monitoring locations.

It is the combination of fixed point monitoring and variable/moveable/portable point surveys that enables a cathodic protection system's performance to be properly assessed. Data from fixed points alone may be insufficient to demonstrate adequate performance.

#### **4.23.5.2 Fixed-Point Data Monitoring Devices**

Potential measurement instruments have been incorporated into what are best described as 'data

recording and management devices,' which enable relatively untrained staff to collect, typically pipe/soil potential data, from fixed test points to a pre-determined schedule. These units will prompt the operator to collect data from particular locations; some will display historical data from that location for immediate comparison in the field and will store the new data for later retrieval and processing. The units incorporate high-impedance digital voltmeters with an integral microprocessor for data and code entries into a solid-state memory. Data and codes are inputted by the use of an  $\alpha$ -numeric keyboard, although auxiliary data may also be inputted via a barcode reader. Barcodes may be used, for example, at test points to store identification data. The units contain real-time clocks and automatically store electronically entered data and time.

#### 4.23.5.3 Pipeline Cathodic Protection Survey Devices

More important has been the development of pipe/soil potential data loggers to undertake close interval pipeline surveys. These surveys are now accepted as the key performance verification tool for cathodic protection of pipelines and enable the measurement of pipe/soil/reference electrode potential at intervals typically of as little as 1 m. Measurements are recorded at each point of both the pipe/soil potential with the cathodic protection system 'ON,' together with the instantaneous OFF potential some 100–300 ms after the cathodic protection current is interrupted (switched 'OFF' at the DC side). This 'instantaneous OFF' potential significantly reduces the IR drop component present in the 'ON' potential measurement, although some element of IR error can remain due to equalizing currents flowing in, on, and off the pipeline.

Best practice systems measure ON and instant OFF potentials and simultaneous ON and instant OFF voltage gradients in what is known as combined digital close interval potential surveys (CIPS) and direct current voltage gradient (DCVG) surveys. These surveys enable not only an accurate measurement of pipe/soil potential at close intervals over the pipeline but also the location and an estimation of the size of coating defects. The data can also be used to calculate fully IR free pipe/soil potentials.

Typical combined CIPS and DCVG data loggers are based on the integration of multichannel high-impedance voltmeters with an electronic solid-state battery-backed memory. Measurements are taken with reference to one of the two parallel connected

'ski-stick' Cu/CuSO<sub>4</sub>(sat.) electrodes for each channel, and utilize a cable connection to a test point facility on the pipeline, **Figures 16 and 17**. The combined CIPS and DCVG surveys may collect the DC voltage gradient longitudinally over the pipeline at a distance of some 3–10 m or transversely to one or both sides of the pipeline. Mobile data logging units are provided with long lengths of light gauge insulated wire to provide the contact between the data logger and the test point and to provide a calibrated distance measurement, with an accuracy normally better than  $\pm 0.1\%$ . The data loggers are capable of time synchronization with additional units, which can be used either for static potential measurements at chosen locations or for 'switching' the impressed-current power sources in the 'ON'/'OFF' mode. The synchronization may be initially established by hard wire between the devices, or increasingly common is the use of the GPS satellite network, which allows accurate and repeat time synchronization and GPS location of the mobile survey position. It is possible to provide an accuracy of synchronization between all units of  $\pm 10$  ms over a 12-h period. Thus, overall, the mobile data logger combines ON and instant OFF pipe/soil potential measurement, ON and instant OFF voltage gradient measurement, with some systems a repeat ON and instant OFF pipe/soil potential measurement for quality audit purposes along with distance, sometimes GPS location, synchronized time together with any codes added to record geographic, topographic, or pipeline/cathodic protection features such as crossing points with other services and test points.

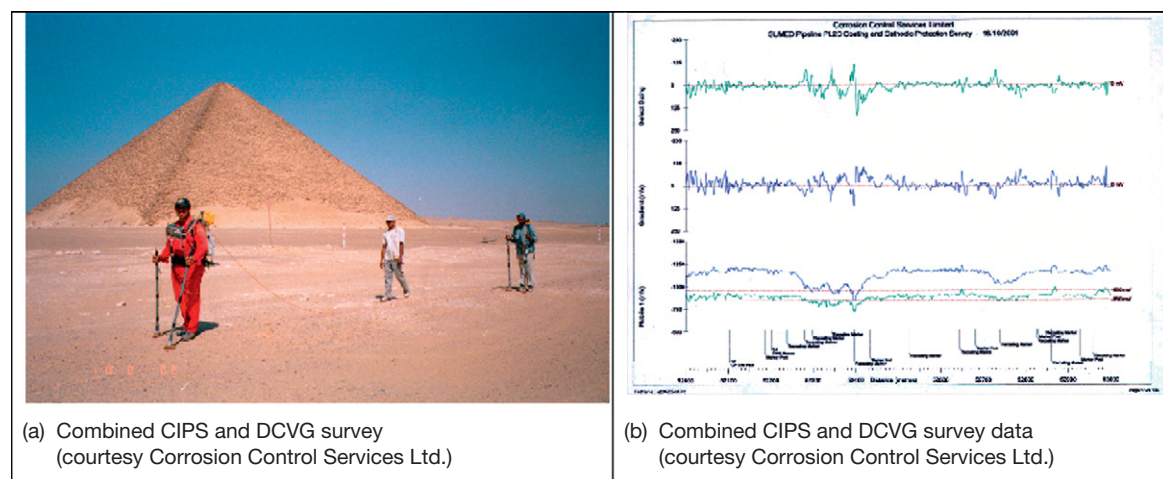

#### 4.23.5.4 Offshore Monitoring and Surveying

For the potential monitoring of offshore oil/gas fixed and mobile jackets and rigs, it is necessary to emplace numerous reference electrodes at all levels on the structure. The hard-wire connections from these electrodes together with, for example, similar connections from specially monitored sacrificial anodes are best terminated and displayed at the surface on 'mimic' display and recording/monitoring panels, **Figure 18**.

Monitoring steel/seawater/electrode potentials can be undertaken on offshore platforms and pipelines by the use of combined reference electrodes and acoustic transponders, thus minimizing the need to rely on vulnerable cabling. The installations comprise remote monitoring units, which may be interrogated by a surface unit. The monitoring units are typically each provided with an Ag/AgCl/

**Figure 16** Principles of combined CIPS and DCVG surveys.

**Figure 17** Buried pipeline combined CIPS and DCVG surveys.

seawater reference electrode and a Zn/seawater electrode both connected to an electronic circuit, comprising two comparators, an encoder and a battery powered transponder, capable of emitting coded

acoustic pulses into the surrounding seawater over an ~10–25-year service-life. The structure connection is made through the watertight housing of the unit, which becomes electrically common to the

structure on installation. The surface unit, which may be located on the platform or a vessel, is used in conjunction with a surface transponder immersed in the sea to activate the data collecting/reference electrode units to transmit their data to the monitoring unit. The structure/seawater/electrode potential information is decoded for presentation on a digital display.

It is normally necessary to locate multiple reference electrodes/data collecting units on a structure. Thus, each unit will only transmit its information on receiving coded instructions. Surface units can commonly accommodate up to 80 different codes. The ability to interrogate and receive over any distance is

dependent upon the acoustic operation frequency. Relatively high frequencies are preferable, as they avoid problems of pulse reverberations and echoes from structural members. Typically, data can be transferred over a distance of 2 km. This type of acoustic unit gives accuracies in potential measurement of  $\pm 10$  mV.

To supplement the fixed point monitoring data, it is normal for fixed and mobile offshore platform jackets and rigs to be surveyed every 1–3 years using divers or, more commonly, remote-operated vehicles (ROVs). These deploy one or more reference electrodes and should have the facility to either/both connect to the structure being surveyed topside

(above the water by means of a cable connection) and to make local ('stab') connections to particular components of the facility that may not be in electrical connection with the main structure (risers, piles, riser clamps, etc.). These surveys, which need to be deployed offshore from diving or survey vessels, are extraordinarily expensive but are surprisingly often poorly specified, do not properly calibrate their electrodes or measuring devices, may even not properly confirm proper connection to the structure, and have even been known to simply measure remote potential data of the survey vessel and not the structure.

For offshore pipelines, continuous potential profile surveys have employed reference electrodes mounted on a 'tow-fish' designed for streamlined towing from a boat traveling along the line of the pipeline. Connection to the pipeline at the originating platform or the shore is maintained by means of a light gauge insulated coated copper or stainless steel wire, and a continuous measurement is recorded of pipe/seawater or seabed/electrode potential along with the position coordinates. Moving at a velocity of  $3\text{--}4\text{ ms}^{-1}$ , the tow-fish carries the reference electrode at a supposed uniform depth and proximity to the pipeline. Typically, in practice however, the reference cell is maintained between 5 and 30 m from the pipe. Thus, the accuracy of the recorded potential is affected by the increasing IR drop as the electrode is remote from the pipe (presenting data that imply better levels of protection than are real) and this technique can only be taken as being an approximate indication of cathodic protection performance.

More accurate pipeline surveys are delivered by using ROVs to accurately place the reference electrodes at known distance from the pipeline. The ROVs carry cameras and magnetometers to detect the pipeline location. Some ROVs have the capability to also 'stab' the pipeline or a galvanic anode fitted to the pipeline, such that local potentials can be measured either to confirm the pipe/sea/electrode potential measurement with the long wire connection to the pipeline (with the IR drop error within the pipe wall which may be significant) or to allow measurements with respect to a remote electrode to be 'calibrated' so that pipe/sea potentials can be estimated without contact to the pipeline.

#### 4.23.5.5 Current Density Devices

The measurement of current densities in the vicinity of a cathodically protected structure has been the subject of standards in continental Europe for many

years in respect of buried pipelines (DCVG as already discussed and the German Rührgas/DIN standard for 'intensive surveys') and has been widely used offshore. These measurements are undertaken by twin electrode devices either installed for stationary use or moved about the structure by diver or remote-controlled vehicle.

The voltage drop required to be measured in seawater to provide current density levels will inevitably be small, and therefore, the difference between the two reference electrodes should also be as small and as constant as possible. A current density sensor designed to overcome this possible source of error utilized two zinc electrodes fixed to a rotating shaft. The zinc electrodes are shielded from water flow by porous material in order to reduce the tendency toward fluctuations in the potentials of the electrodes. The sensor assembly provides two signals that are separated by a filter: a sine signal produced by the cell rotation and the signal due to the difference between the potentials of the two cells. Both these signals are amplified and recorded at the surface. Competing systems utilize more accurate Ag/AgCl/0.5 M KCl reference electrodes in a defined array. These data are equivalent to the DCVG data measured between two reference electrodes in buried pipeline surveys as already detailed. With computerized mathematical modeling using finite element analysis, calculated estimates may be made in respect of galvanic anode current outputs, predicted anode life, and the presence of defects in the structure coating.

## Glossary

**Activation energy** Characterizes the slope of temperature dependence of the reaction rate (expressed by, e.g., current density  $i$ ) in the coordinates of  $\log i - 1/T$  according to the Arrhenius equation.

**Anodic protection** Means an electrochemical protection (corrosion protection achieved by electrical control of corrosion potential) by increasing the potential to the stable passivity range.

**Breakdown potential** Means a potential, above which the passive metal dissolves by pitting.

**Free corrosion potential** Means a corrosion potential in the absence of external electrical current flowing to or from the metal surface.

**Passivation current density** Means a current density at the passivation potential.

**Passive current density** Means a current density within the passive range.

**Passivation potential** Means the lower limit of the passive range separating the active potential range from the passive one.

**Passive range** Means a potential range where passivity prevails.

**Protection potential** Means a potential value, at which the corrosion rate becomes acceptable.

**Transpassivation potential** Means a potential, above which a passive metal gets uniformly activated and dissolves as ions in a higher oxidation state.

## Abbreviations

**AP** Anodic protection

**b.p.** boiling point

**FeCr18Ni10(Mo)** Stainless steel with 18 wt% Cr, 10 wt% Ni alloyed with Mo

**m.p.** melting point

**SCC** Stress corrosion cracking

**SHE** Standard hydrogen electrode

## Symbols

$E_{\text{corr}}$  Free corrosion potential (V(SHE))

$E_{\text{prot}}$  Protection potential (V(SHE))

$E_a$  Activation energy ( $\text{kJ mol}^{-1}$ )

$E_b$  Breakdown potential (V(SHE))

$E_p$  Passivation potential (V(SHE))

$E_t$  Transpassivation potential (V(SHE))

$i_{\text{cc}}$  Passivation current density ( $\text{A m}^{-2}$ )

$i_p$  Passive current density ( $\text{A m}^{-2}$ )

$W$  Concentration (wt%)

$\Delta E$  Passive range (mV)

$\gamma$  Specific conductivity ( $\text{S m}^{-1}$ )

## 4.24.1 Introduction

The first practical use of anodic polarization for corrosion protection was demonstrated by an English author, Edeleanu,<sup>1</sup> in 1954. However, the principle of anodic protection (AP) had been mentioned in USA patents<sup>2</sup> already in 1945. Along with Edeleanu's work, another study on AP was published by Russian authors, Novakovsky and Levin.<sup>3</sup> The passivation by current was also proposed in the dissertation of Cernova (1954), published later with Tomasov<sup>4</sup> in 1955. The first commercial application of the industrial AP is alleged to have taken place in the USA in 1958.

More than 50 years after the first rational experiments to use anodic polarization for the deceleration of corrosion rate of passivable metals, due to the change in corrosion potential, the use of AP in industrial applications was established for corrosion systems such as carbon steel in sulfuric acid and alkaline environment, and stainless steel in sulfuric acid. This means that in cases where AP stood up to the competition of other corrosion protection methods despite its relative operation complexity and a certain degree of risk. Considering the perspective of an industrial user, AP possesses, besides indisputable advantages, a general disadvantage of the necessity to continuously monitor a due operation of the system, since any failure of the regulating circuits can lead to an extremely fast damage of the protected equipment. It is because the corrosion

rate of many corrosion systems, for which the AP is very effective in laboratory or semioperating conditions, is absolutely unacceptable outside the passive range, even for a short while. Such corrosion systems failed in long-term practical applications.

The essential difference between anodic and cathodic protection is in the degree of risk. The failure of cathodic protection is tolerable for a longer period of time and does not lead to a sudden damage of the protected equipment. Similar to the AP, the protective effect of cathodic protection is also frequently given by the formation of a passive layer. As for the cathodic protection, it is caused by composition changes in the superficial electrolyte during cathodic polarization of steel in neutral environment, where cathodic passivation occurs due to alkalization induced by the limited environment convection. Another difference between both types of corrosion protection lies in the aggressiveness of the corrosion environment. Cathodic protection is mostly used in relatively benign environments, frequently as a complementary protection method to coatings, whereas the AP is applied in a strongly aggressive environment as a fundamental protective measure. If we compare current needs per metallic surface unit that is in contact with the electrolyte, there is no substantial difference between the two types of electrochemical protection.

The AP is usually understood as a method consisting in the use of polarization to shift the protected metal from active to passive state, which is usually connected with high current demands to exceed the passivation potential. However, this understanding does not apply to corrosion systems with successful operation applications. Long-term success is typical for applications where a metal tends to passivate spontaneously in a given environment or where spontaneous passivation occurs under low temperatures and where anodic polarization in the passive range further increases the corrosion resistance of the metal. In such cases, there is no longer any need to use high currents for passivation, and many problems relating to the throwing power of AP and the danger of damages to shadowed spaces and attached equipment are thus eliminated. Another great advantage is that an accidental failure of the proper operation of the regulating circuits does not lead to a fast catastrophic increase of metal corrosion.

There are approximately 400 literature references dealing directly with AP, but most frequently, they only describe results from experimental laboratory experiments – long-term operation experience is

rather rare in the literature. Although the AP has become a standard part of technological sets, there are only few details available, because it is a part of business know-how.

The overview of industrial applications of AP was published by a German author Gräfen<sup>5</sup> in 1971. Monographs on AP summarizing most of the specialized literature were published in the 1970s and early 1980s. Rather extensive Russian chapter by Makarov<sup>6</sup> from 1974 refers to publications back to 1973 and the American monograph by Riggs and Locke<sup>7</sup> from 1981 has a bibliography dating back to 1790. The Russian work of Kuzub<sup>8</sup> from 1984 contains references back to 1981 and Novák's Czech monograph<sup>9</sup> from 1987 refers back to 1983. The overview of later Russian information can be found in summarizing articles by Agafonova and Makarov<sup>10</sup> of 1989 and Kuzub<sup>12</sup> of 1991. German experience with 30 years of industrial application of AP is summarized by the work of Gräfen *et al.*<sup>11</sup> dated 1991, Czech operation experience with 25 years of industrial application of AP is briefed upon in the study of Novak and Mokra<sup>13</sup> dated 2006.

Literature data from the past 25 years are rare and the number of relevant references is estimated in tens. There have been no breakthrough suggestions that would expand substantially the application area of AP. Another big problem of specialized literature is that the inclusion of many literature references under the entry of 'anodic protection' is unjustified. Many literature references under this entry fail to comply with the definition under the ISO 8044 terminology standard – "Anodic protection is electrochemical protection (corrosion protection achieved by electrical control of corrosion potential) by increasing the potential to a value corresponding to the stable passive state" – and deal generally with the use of passivation to protect metals or, for example, sacrificial anodes, and recently, also conductive polymers, the function of which is assumed to be similar to that of cathodic alloying elements or AP by protectors.

The main purpose of AP use is to ensure sufficient resistance of passivable metal against uniform and localized corrosion. The effectiveness of AP cannot be simply expressed by comparing corrosion rates of protected and unprotected materials, since the particular material cannot be used without AP under given conditions. The effectiveness must be assessed in light of the comparison of various corrosion protection alternatives that ensure technically acceptable resistance in the required construction arrangement.

Prolongation of a service life of anodically protected equipment does not have to be the biggest benefit, though the corrosion resistance is the basic qualification. The same applies to, for example, the requirement for high purity of a manufactured or stored product. The necessity of a pure environment is the reason why AP is applied to storage tanks for sulfuric acid.

Limitations of production technology caused by low corrosion resistance of the production equipment can be mitigated by AP application. Intensification of the sulfuric acid production by increasing the operating temperature could serve as a good example.

Very slow corrosion rate under AP enables better and long-term use of metallic materials, and sometimes it is possible to ensure sufficient service life of less costly materials, which limits the use of precious metallic and nonmetallic structure materials.

Thanks to AP, it is possible to construct devices with better parameters representing new ways of technological solutions, such as an effective consumption of heat energy, which, without AP, is wasted in the cooling process during the sulfuric acid production.<sup>14,33</sup> Coolers of concentrated sulfuric acid are nowadays the most effective application.

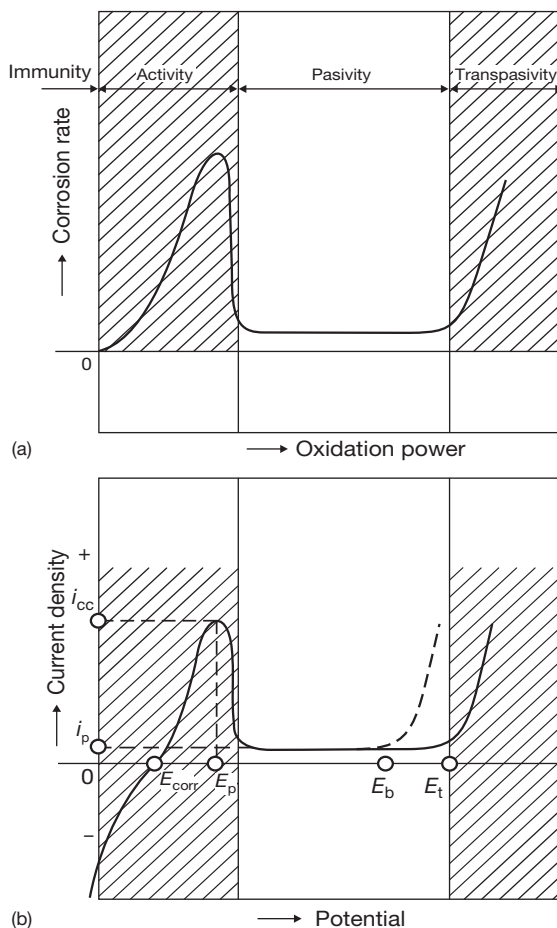

Secure and reliable operation of anodically protected equipment consists not only in minimum corrosion, but also in, for example, the prevention of undesirable evolution of hydrogen during the acid storage.

AP can be also used in nonaqueous environments, when their electrolytic conductivity is high, for example, in glass melts where heating electrodes can be thus protected from corrosion.

AP can also be applied in areas that are not related to corrosion, for example, in the prevention of undesirable deposition of nickel on the device walls during the electroless nickel plating process. In addition to the enhancement of work productivity, this application increases material savings.

#### 4.24.2 Passivity of Metallic Materials

The corrosion rate of most metals grows with the increasing environment oxidizing power (Figure 1(a)). Once the oxidizing power reaches a given threshold, a steep drop of the chemical reactivity of various metals can be observed. This phenomenon was first described more than two centuries ago, but the mankind had been encountering it in practice since the beginning of the use of nonnoble metals. This process

**Figure 1** (a) Dependence of passivable metal corrosion rate on the electrolyte oxidation power. (b) Polarization curve potential-current density ( $E_{corr}$  – free corrosion potential,  $E_p$  – passivation potential,  $E_b$  – breakdown potential,  $E_t$  – transpassivity potential,  $i_{cc}$  – passivation current density,  $i_p$  – passive current density).

is called passivity, and in the corrosion perspective, it is a totally positive process, which substantially slows down the course of electrochemical metal dissolution.

Passivability means the rate of difficultness of transforming a metal in a given environment from active to passive state. It is characterized by the values of passivation potential ( $E_p$ ) and passivation current density ( $i_{cc}$ ) (Figure 1(b)). Corrosion resistance in a passive state and the stability of the passive state are given by the values of passive current density and the width of a passive range ( $\Delta E$ ), that is, the potential difference between the potential of full passivity (is a bit more positive than the passivation potential) and the transpassivation ( $E_t$ ) or breakdown potential ( $E_b$ ). Factors affecting the passivability ( $E_p$ ,  $i_{cc}$ ) and the stability of

passivity ( $\Delta E$ ,  $i_p$ ) are almost identical though their influences can apply in different ways. Properties of a metal that apply to such case include composition, structure, internal stress, and superficial state. When it comes to the properties of environment, factors that matter are, particularly, composition, concentration, temperature, and flow. Construction, time of exposure, and polarization are other factors that apply.

Passive metals that we encounter the most enter the solution usually in the form of  $\text{Fe}^{3+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cr}^{3+}$ , and  $\text{Ti}^{4+}$  ions. According to the Faraday's law, it is possible to make the calculation of corrosion rate from the passive current values, on condition that the only reaction participating in the measured current is the anodic dissolution of the passive metal. In a gross estimate, the value of current density in ampere per square meter corresponds approximately to the corrosion rate in millimeter per year.

Considering the mechanisms, the processes leading to passivation of metal can be divided into three basic groups: passivation by influencing cathodic process, passivation by influencing anodic process, and passivation by changing an electrode potential by polarization from an external current source.

Passivation by influencing cathodic process can be achieved either by the addition of substances that get easily reduced at potentials in a passive range of the metal, or by the facilitation of the reduction of the environment elements by connecting the protected passivable metal to or alloying it with metals that have only small overvoltage of cathodic reaction and greater current density of such reaction. Even an extension of the area of the connected cathodic material can lead to passivation of passivable metal in an environment with sufficient oxidizing power. The oxidizing power of the environment is characterized by the oxidation–reduction potential on the one hand, and by the value of exchange or limiting current density on the other hand.

Passivation by influencing anodic process can be achieved by alloying with metals that shift the passivation potential in the negative direction or with metals that reduce anodic dissolution in active state, passivation current density. The passivation is also facilitated by the addition of substances (in the corrosion environment) that decelerate the anodic dissolution of the metal, or by the removal of corrosion stimulators from the solution.

The change of electrode potential by polarization from an external current source is a procedure enforcing a potential lying in an area of low corrosion rate to the metal, without any influence on the anodic or

cathodic dependence. If this is achieved by cathodic polarization (shifting the corrosion potential in a negative direction), we talk about cathodic protection; if it is achieved by anodic polarization (shifting the potential in a positive direction) into the passive range, we talk about AP.

Intervention in a corrosion system frequently affects both cathodic and anodic processes. Both procedures are exploitable to facilitate passivability in AP.

Several types of potential–current curves (**Figure 2(a)–(d)**) can be the result of oxidizing effect of the environment on the passivable metal:

Type-I – the oxidizing ability of the environment is low to passivate metal and retains it in the activity range. AP can be used for passivation (**Figure 2(a)**).

Type-II – the oxidizing ability of environment suffices to retain the metal in the passivity range, but is insufficient to passivate an active metal. The passive state is unstable. The AP can be used for passivation (**Figure 2(b)**).

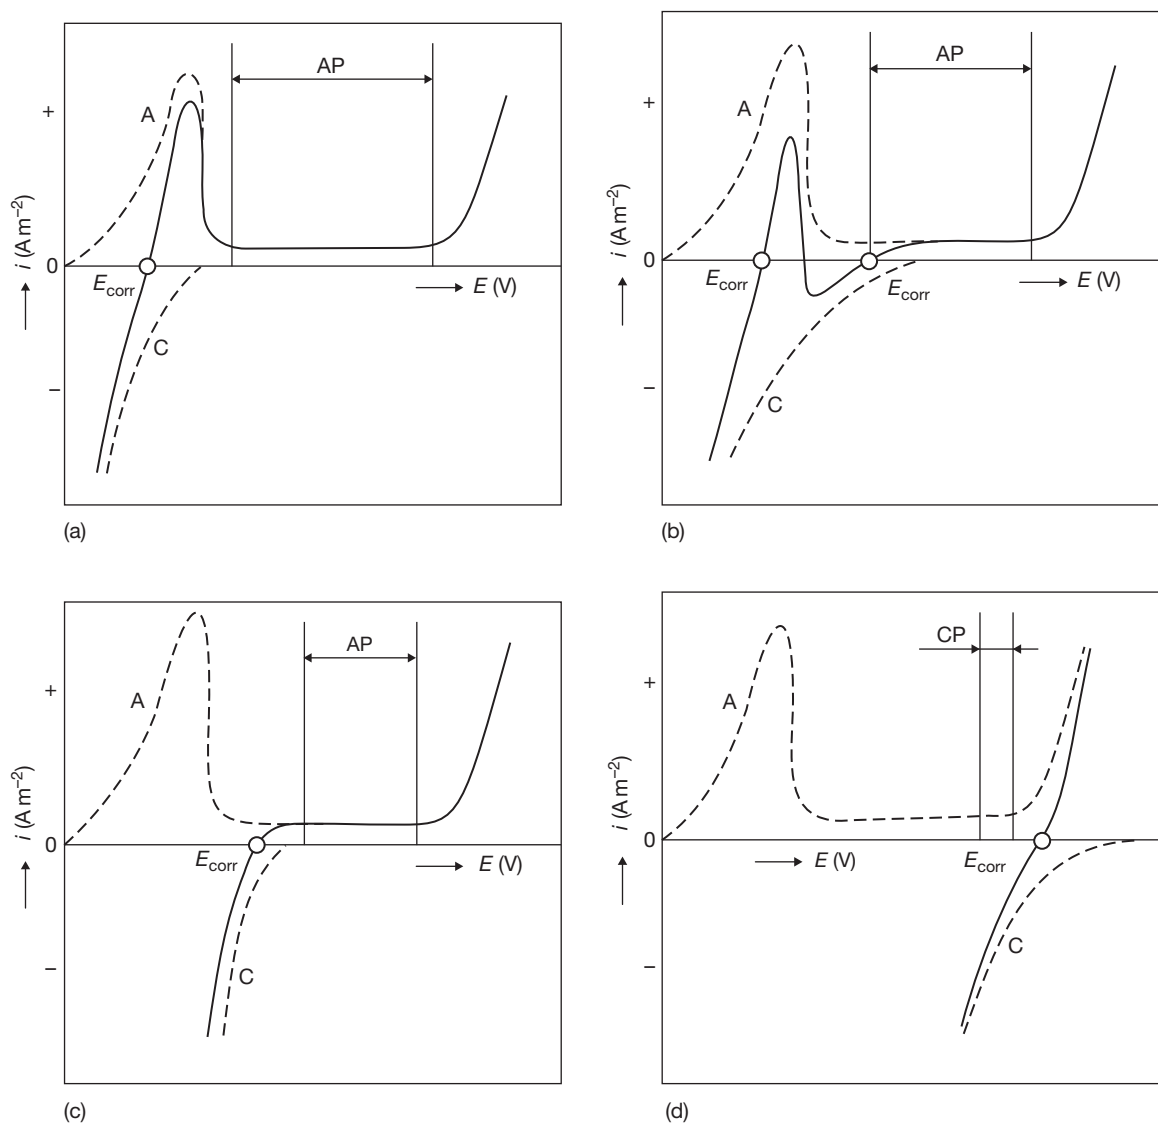

Type-III – the oxidizing ability of the environment suffices for spontaneous passivation and the passive state is stable, if there is no occurrence of localized forms of corrosion. In case of threatening localized corrosion, AP can be used for positive potential shift to the range of stable passivity (**Figure 2(c)**).

Type-IV – the oxidizing ability of the environment is high; corrosion and pitting corrosion occur in the area of transpassivity or beyond the breakdown potential, respectively. Cathodic protection can be used for polarization into a stable passive range (**Figure 2(d)**).

Transition between particular types of dependencies in a specific corrosion system can be caused by temperature or a presence of small amounts of specific substances in the basic corrosion system.

As for the practical applications of AP, carbon steel, stainless steel, and titanium are the most important metallic materials. Passivability of iron alloys is influenced the most by chromium, which significantly facilitates passivation if the addition exceeds 12%. The mechanism of chromium effect can be explained by the shift of the passivation potential in the negative direction and the decrease of a passivation current density. Iron alloys containing chromium in excess of 12% (stainless steels) are resistant against corrosion in many environments just because of simple passivability. Nickel applies to iron–chromium alloys where it reduces passivation current

**Figure 2** Different types of potential–current cumulative curves as a result of electrolyte oxidizing effect on the passivable metal. (a) Type-I – the oxidizing ability of environment is low to passivate metal and retain it in the activity range. AP can be used for passivation. (b) Type-II – the oxidizing ability of environment suffices to retain the metal in the passivity range, but is insufficient to passivate an active metal. The passive state is unstable. The AP can be used for passivation. (c) Type-III – the oxidizing ability of environment suffices for spontaneous passivation and the passive state is stable if there is no occurrence of SCC. In case of threatening SCC, AP can be used for a positive potential shift to the range of stable passivity. (d) Type-IV – the oxidizing ability of environment is high; corrosion and pitting corrosion occur in the range of transpassivity or beyond the breakdown potential, respectively. Cathodic protection can be used for polarization into a stable passive range.

and corrosion in an active state. The addition of molybdenum increases the stability of a passive layer on stainless steels against crevice and pitting corrosion, in particular.

Titanium is also alloyed (by Al, Cr, Mo, Fe, V, Mn, Sn, Zr), but we can say that none of these elements substantially improves passivation properties of titanium. But alloying with cathodic alloying elements

such as platinum, palladium, etc., has the greatest influence on passivability of titanium and its alloys. These metals reduce the overvoltage of cathodic reaction. In commercial production, titanium is made with 0.2% of palladium. Cathodic alloying leads to autopassivability of metal and applies to stainless steels too (Cu in FeCrNiMo alloys). An autopassivable metal shows polarization curves of the Type-III

(see **Figure 2(c)**) and can be used for AP to eliminate crevice corrosion.

In addition to the composition, the structure of metal is another important factor. The structure can be influenced by both composition and heat or mechanical treatment of the material. The impact of structure applies the most to different chemical composition of structural phases, which causes great differences in passivability. The origination of structural inhomogeneity of metal leads to the reduction of a passive range and to the increase of characteristic currents. This usually results in the occurrence of localized forms of corrosion attack, such as intergranular or pitting corrosion. Materials with homogeneous structure are easier to passivate and show better resistance in a passive state.

Weld seams usually belong to the most critical parts of a majority of metallic equipment. Passivability of a weld seam or heat-affected areas is given, again, by the homogeneity of chemical composition. An inhomogeneous weld seam or chemical composition that fails to ensure sufficient passivability can lead to localized forms of corrosion or cause earlier corrosion of the weld seam material. However, for good passivability and resistance in the passive range, it is not necessary to have an identical chemical composition of the weld and the basic metal. The only prerequisite is to keep the corrosion or protection potential within the overlaps of passive ranges of all metals concerned.

The galvanic connection of passivable metal and a noble material that spontaneously achieves a potential in a passive range and at the surface of which reduction proceeds with lower overvoltage leads to passivation. Depending on the area of the cathodic material surface, the connection results either in spontaneous passivation (**Figure 2(c)**, curve type-III), or more frequently, in a curve of the type-II (**Figure 2(b)**), at which there are two corrosion potentials in both active and passive state. The corrosion rate accelerates in the activity. Noble metals, such as platinum, palladium, copper, silver, and in some environments, other metals, graphite, and also some electrically conductive metallic oxides can be used as a cathodic material.

#### 4.24.3 AP and Localized Forms of Corrosion

##### 4.24.3.1 Pitting Corrosion

Pitting corrosion is, under the conditions of anodic polarization by an external source of current, noted

for several peculiarities compared with the corrosion in a redox system at identical potential. Migration of aggressive ions to the places of intensive anodic dissolution is much more significant, because the polarization current concentrates on the top of the pit. Therefore, the pitting attack can be more frequent and more intensive on an anodically polarized surface than on the nonpolarized surface.

The fact that pitting corrosion is bound to the existence of a passive layer on the metal surface and that it is accelerated by anodic polarization represents a serious problem for AP in the presence of aggressive anions. The anions that cause damage to the passive layer, which subsequently leads to the pitting corrosion, are predominantly chlorides.

Growing concentration of an aggressive ion makes the breakdown potential shift in a negative direction, increases the passivation current, and narrows the stable passive range. In addition to the damage of the passive layer above the breakdown potential, aggressive anions cause the growth of current in the stable passivity, which somewhat decreases the protection effectiveness. Even the passivation of active surfaces is aggravated in such environments as a result of higher passivation current density. The proportion between activities of the basic nonaggressive anion and the aggressive anion that causes pitting significantly affects the width of a stable passive range. The growth of concentration of anions with weaker passivation effect ( $\text{OH}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{PO}_4^{3-}$ ) makes the breakdown potential shift in the positive direction. Laboratory data on limitations of AP given by its application in environments with aggressive ions are available predominantly for stainless steels in sulfuric acid solutions containing chlorides. Besides aggressive anions, corrosion environment can contain anions with inhibiting (passivating) effects as nitrates. In such a case, the stable passive range can exist at potentials more positive than the breakdown potential, and the AP can thus be used for protection against pitting corrosion. This phenomenon enables the AP to effectively prevent pitting corrosion of stainless steels in nitrate environments in the presence of chlorides.

##### 4.24.3.2 Intergranular Corrosion

The reason for intergranular corrosion is a structural and chemical inhomogeneity of metal at a grain boundary. Preferential dissolution of less-resistant metal and phases at the grain boundary leads to the intergranular propagation of corrosion. This type of

localized corrosion proves to be the most significant for heat-treated and welded stainless steels.

Considering the AP utilization in equipment made of stainless steels after sensitization-inducing heat treatment (e.g., after welding), it is essential to choose a protection potential within the range where active–passive or transpassive–passive type of intergranular corrosion is avoided. The reduction of the usable passive range from the side of activity is given by the degree of the grain boundary depletion; from the side of transpassivity, it is given by the number of phases in the structure that show low corrosion resistance at high oxidizing potentials. The optimal protection potential constraining intergranular corrosion of austenitic stainless steels, such as FeCr18Ni10 in sulfuric acid, ranges from 0.5 to 0.8 V(SHE). It was experimentally proved that sensitized samples, which are highly susceptible to strong intergranular corrosion, remain unattacked if protected by AP. Nevertheless, these findings are based on relatively short laboratory experiments, during which the passive–passive type of intergranular corrosion had no chance to show up more significantly. Therefore, it is necessary to ensure a sufficient resistance to intergranular corrosion not only by a due choice of the protection potential, but also by the appropriate metal composition and structure that weaken the susceptibility to passive–passive intergranular corrosion. The best solution is to use pure materials, that is, steels with a very low content of carbon, ensuring resistance against common types of intergranular corrosion. Practical experience shows that the AP can prevent intergranular corrosion, which occurs for example, in the vicinity of weld joints.

#### **4.24.3.3 Stress Corrosion Cracking**

The finding that stress corrosion cracking (SCC) is bound to the existence of a passive layer on the metal surface and that it is accelerated by anodic polarization led to a misleading generalization that the AP creates conditions for this type of localized corrosion attack.

Even the authors of first AP works were aware of the danger of SCC and observed experimentally the effect of the passive-range directed polarization on the susceptibility of mechanically stressed samples to SCC. This research was especially noted for demonstrating that the AP is a recommendable way to eliminate corrosion in environments where SCC occurs without polarization. It relates particularly to carbon, or low-alloyed steel in sodium or potassium

hydroxide or ammonium nitrate, in Kraft liquor, and stainless steel in sulfuric acid with a low content of chloride ions. For AP, it is important to know that SCC is bound to the potential range of instability of a passive layer, that is, to the bordering area between the active and passive state and to the range of a damaged passive layer at higher potentials.

It is possible to apply AP to prevent hydrogen embrittlement of iron alloys in the acrylonitrile synthesis environment, and the negative effect of hydrogen on carbon steel in the concentrated sulfuric acid environment can also be eliminated by the use of AP. Generally, anodic polarization can eliminate all kinds of negative effect of hydrogen, which evolves in electrolytes on metallic surfaces.

#### **4.24.3.4 Erosion–Corrosion**

Erosion–corrosion is a process accelerating corrosion by mechanic damage of metallic surface in an aggressive environment. Erosion can be caused by the presence of solid particles in a corrosion environment or by a turbulent flow of liquid. Erosion can be also caused by gas bubbles. Erosion of metallic superficial layer is typical for materials, the corrosion resistance of which is given by the effect of their passive layer. This fact implies other limitations of the use of AP in erosive environments. The biggest problem with corrosion–erosion attack is the level of an acceptable erosive effect of a liquid stream on the anodically protected surface, at which the corrosion rate would be technically acceptable.

Mechanical resistance and solubility of the forming passive layer are important features. If the layer is formed predominantly by salts, the drop of protective effect can be observed even in the area of the laminar liquid flow. It applies particularly to anodically protected carbon steel in concentrated sulfuric acid where corrosion is 2–10 times faster even at low liquid speeds. The flow occurring in the laminar area was detected to have no effect on the corrosion resistance of passive surface of materials, the protective layer of which consists of oxides (e.g., stainless steels).

The stability of the stainless steel passive state in flowing 93–99% acid strongly depends on a weak contamination of the acid by iron ions. The iron content and acid temperatures are the decisive factors of the potential–current type of dependency. (Figure 2) To achieve effective AP, the minimum concentration of iron ions in flowing sulfuric acid (98.5%) at 100 °C must be 7 ppm (solubility of ferric sulfate). The stability of the passive sulfate layer

during acid flow is conditioned by the origination of trivalent iron compounds, whose solubility in concentrated acid is approximately by two orders lower than that of bivalent iron compounds. Spontaneous passivation results in the formation of  $\text{Fe}^{2+}$  sulfate passive layer, while anodic polarization above 0.85 V(SHE) leads to the formation of  $\text{Fe}^{3+}$  sulfates. This is the reason why cooling systems with AP do not need any significant limitations of acid flow rate and why erosion–corrosion does not occur in them, in contrast to systems without AP.

The erosion effect of a corrosion environment can be caused by solid particles in the corrosion environment, penetrating the equipment as impurities or given by the technology (e.g., ore leaching), or formed during the production process (e.g., crystallization of salts). Besides the mechanical and chemical resistance of the passive layer is important repassivation rate, the decisive factors comprise the rate and the angle, at which the particles strike the surface, their hardness, weight, concentration, and shape. Erosion effect of solid particles in a liquid can preclude the application of AP even where allowed by the composition of the basic solution.

The reaction mixture prepared during fabrication of formic acid where crystalline ammonium sulfate is formed can serve as an example. Under model conditions corresponding to the operational mixing of the reaction mixture, the passive current density increases by three orders of magnitude compared with the state without mixing. In consequence, the corrosion rate grows to a technically unacceptable value.

#### 4.24.4 Anodically Protected Objects

##### 4.24.4.1 The Basic Requirements for Protected Equipments

Metallic parts of an object suitable for the AP must be made of passivable metal showing an acceptable corrosion rate in a passive state (usually  $<0.1 \text{ mm year}^{-1}$ ) under the operation conditions. This applies also to all other metallic parts that are conductively connected to the protected equipment and are placed in the same corrosion environment. The best thing would be that the whole equipment is made of a single material. If possible, the equipment should be free of any shadowed spaces that may cause difficulties, namely narrow crevices. Therefore, it is necessary that the equipment is welded rather than put together with joints where crevices may appear, for example, under sealing. For the same reason,

it is not advisable to anodically protect coated surfaces. Weld seams must be perfect, with no pores or cracks.

The inlet and outlet pipes, closing elements, and attached devices must be, if essential for the environment, protected against an undesirable side effect of AP. AP of functional shadowed spaces (e.g., inside the pipes, spaces between desks) is possible, if the throwing power is respected.

The construction of the equipment must allow installation of one or more reference cathodes in places that are suitable for reliable regulation of protection potential throughout the entire equipment.

Since AP is effective only below the electrolyte level, it is desirable to keep the protected surface completely immersed. Therefore, it is highly recommended to have completely filled, continuously working equipment where no spaces filled with gas could occur. Most equipment fails to live up to this requirement, and still, it is possible to have them effectively protected. However, it is necessary to take into consideration that the surface emerging above the electrolyte level is left unprotected. Therefore, it must be made sure that the stability of a passive state in the electrolyte film above the level was sufficient. If the level is stable for a longer period of time, its negative effect can be eliminated by construction adaptation.

If the level varies, it is advisable that a minimum level of liquid remains in the equipment so that electrolytic connection between the protected object, cathode, and reference electrode is ensured. If the equipment must be completely drained from time to time, the arrangement of operation technology must enable easy passivation when refilling the equipment. It is difficult to ensure reliable AP in equipment where a part of the metallic surface is in contact with the electrolyte film only. Moreover, the equipment construction should eliminate the erosive effect of a flowing environment as much as possible.

##### 4.24.4.2 Types of Protected Objects

Heat exchangers and storage vessels are the most frequently anodically protected objects, which we have long-term operation experience with. These objects are in continuous operation. However, discontinuously operating objects can be anodically protected as well, even those that are completely drained, for example, digesters, stripers, measuring vessels, and various reactors. Most of the equipment, except for storage and transportation vessels, operates under elevated temperatures, usually above  $100^\circ\text{C}$ ,

sometimes even more. AP in melts is feasible even at much higher temperatures.

The equipment, such as autoclaves or kraft digesters, operates under elevated pressure. In many objects, there is a rather small motion of liquid, but in heat exchangers, the flowing rate can reach units of meters per second.

The volume of protected objects ranges from units to 10 000 m<sup>3</sup> and the protected area from units to thousands square meter.

The remarkable thing about AP is that it proved useful even for very complicated equipment and it was used to protect the inner surface of pipes. The level of complexity of protected equipment is given particularly by conductivity and by the aggressiveness of the corrosion environment.

#### 4.24.4.3 Throwing Power of AP

If a metallic surface is polarized by an external source of current, the potential drops as a consequence of the current passage through electrolyte. This drop is especially significant with the polarization of active metal in shadowed areas, such as crevices filled with electrolyte or at pipe inlets to the protected equipment.

The protected surface is polarized to the protection potential in a passive range, and as getting deeper into the interior of the shadowed area, the potential drops from this value to more negative values. If the distance is long enough, it can reach the value of a free corrosion potential in active state. The potential interval between protection potential and free corrosion potential (in active state) comprises the potential, at which the corrosion rate of the metal equals the passivation current density, which substantially exceeds the corrosion rate at the free corrosion potential. This problem has been addressed by a number of authors.<sup>15,16</sup>

The current distribution within anodically protected equipment is described by mathematical relations referred to in literature.<sup>17–23</sup>

To express quantitatively the said dependencies, it is necessary to know the shape of the polarization curve, potential dependence of the corrosion rate, geometry of the shadowed area, and the conductivity of the electrolyte.

Relations were derived not only for the throwing power and formation of crevice corrosion under the conditions of anodic polarization, but also for the anodic passivation at the liquid level, for the passivation of continuously filled vessels and to calculate

the parameters of measures to be taken to eliminate the undesirable effects of AP, resulting from the limited throwing power.

Generally, the throwing power of AP applied to completely passivated surfaces (which is the prerequisite of proper operation) is extraordinarily high compared with the throwing power of cathodic protection applied to the same geometry.

Considering the throwing power of AP of complicated constructions containing shadowed areas of critical dimensions, it is more advisable to apply a permanent potentiostatic polarization that secures safer operation and enables protection of more complicated equipment with a minimum number of cathodes.

If the length of the piping connected to the protected equipment exceeds critical dimensions and cannot thus be passivated by current from the cathode placed in the protected equipment, it is important to take measures eliminating undesirable corrosion of the attached device. If it is feasible to ensure reliable electric insulation of the protected equipment from grounded parts, the attached devices will be preserved from the negative effect of AP. However, most objects are grounded, and thus, conductively interconnected. There are a number of compatible procedures that can reduce the negative effect of AP, such as the passivation by auxiliary cathodes, passivation in an environment with better oxidizing power, passivation in a less aggressive environment (concentration, temperature, and composition), passivation at high positive potentials, and the use of an insulation section and a section with an intentionally induced potential drop.<sup>24</sup>

To prevent crevice corrosion under the conditions of anodic polarization, it is essential to avoid the formation of crevices by a suitable construction of the equipment, widen the crevice where necessary, or use self-passivating materials in places where crevices are unavoidable, or materials that show a low passivation current density and a narrow activity range in the given environment.

#### 4.24.4.4 Influence of the Level on the AP Effectiveness

The effect of AP is limited to the surface below the electrolyte level and practically ends at the electrolyte–atmosphere interface. Similar to crevices, the AP cannot ensure passivation of the metal by a thin layer of electrolyte (a film of electrolyte on walls) due to the ohmic drop during the passage of passivation

current. If the surface below the level is passivated and the environment aggressiveness does not lead to a spontaneous activation, the undesirable effect of the level does not show up. Nevertheless, if the passive state stability above the level is low or lowered by the effect of atmosphere (humidity, gases with activating effect), corrosion may grow similar to the shadowed areas.

The problem with the liquid level is even more significant if the surface coming through the level transfers heat. That is the case of heating coils, desks, and incompletely filled heat exchangers. The most effective measure is to prevent the level to get in contact with the protected surface, which can be achieved by the complete filling of the equipment, the removal of spaces filled with gas, or by placing the entire protected surface below the liquid level. The negative effect of the liquid level is caused not only by the film of electrolyte on the walls, but also by accumulated deposits. This happens if the liquid level is in the same position for a long period of time, the electrolyte is not changed or mixed, and the corrosion products have low solubility in the environment. In practice, however, the liquid level fluctuates and is mixed regularly, and the electrolyte gets changed.

Relations derived for the continuous passivation of an active surface above the liquid level is noted in particular for the start-up modes.<sup>25,26</sup>

When the anodically protected equipment with activated surface above the liquid level is filled continuously, current is predominantly given by the ratios in the film of a corrosion environment above the level, where the potential gradually changes from the free corrosion potential in activity to the protection potential in passivity. The current is essentially independent of the mass of the electrolyte in the equipment (the size of immersed surface), which indicates that the main portion of the passivation current passes in the film of the corrosion environment closely below the liquid level in the active section that forms, similar to the shadowed spaces, as a consequence of the ohmic drop in the electrolyte level. Changing the electrolyte level in operating conditions, where metallic surface below the liquid level activates spontaneously, is mostly unacceptable for the use of AP.

#### 4.24.4.5 AP at Heat Transfer

At present, sulfuric acid coolers and other types of heat-transferring devices are the most widespread

anodically protected objects. The principle of most of such objects is that the protected surface has different temperatures in different places. Since temperature substantially affects the passivation properties and the passive state stability, the nonisothermal surface represents a serious heterogeneity, considering AP. It complicates, in particular, the estimate of currents for AP of the equipment on the grounds of laboratory tests.

Model tests showed that the stability of a passive state on a nonisothermal surface is given by the warmest part, which tends to activate the most. Even the current demands for the protection of the warmest parts are higher than for the colder ones. It must be taken into account when constructing cathodes that they should be placed preferentially in the vicinity of the warmest places. Current demands in colder places of the surface are lower.

Heat-transferring devices should not be anodically protected in conditions where the corrosion environment is boiling. Boiling may constrain the electrolytic connection between the protected surface and the corrosion environment, which may cause a situation in which the surface is not protected by current for some time. Emerging bubbles may induce the formation of crevices and undesirable spaces filled with gas. The boiling of the film may result in a complete loss of the electrolytic connection. The surface can thus get excessively overheated and activated, and the corrosion rate in passivity can grow tremendously. Overheating of the surface above the liquid level induces activation and excessive corrosion close above the liquid level. Generally said, neither the heat transfer nor the formation of nonisothermal conditions on the immersed surface reduces the effectiveness of the AP, but boiling is undesirable for the protected surface.

#### 4.24.5 Modes of AP

Anodically protected objects can be operated in three basic modes. The passivation takes place in a start-up mode, in which the protected surface potential shifts from the free corrosion potential to the protection potential in the passive range and current or the frequency of current switching is stabilized. The AP itself is applied under the conditions of an operation mode when the potential of the object is maintained at the required level in the passive range. Security, even during the main power supply and potential controller failure, is ensured by an emergency mode

that temporarily prevents the potential from shifting to the active range.

#### 4.24.5.1 Start-Up Modes

The metallic surface of new unfilled devices is mostly covered with an oxide layer formed in air. Although this layer exerts certain protective effects, it depends on the aggressiveness of the operation electrolyte, if it resists after the first filling. The resistance of this layer is usually insufficient and fits only for low-aggressive environments.

To passivate an initially active surface, a minimum value of direct current is needed, which is expressed by the value of passivation current density. The order of magnitude  $i_{cc}$  for common corrosion systems ranges from 10 to 1000 A m<sup>-2</sup>. It is thus obvious that it is usually impossible to passivate the entire protected surface by current under the operation conditions, because it would require very strong current sources. That is why it is necessary to apply the following procedures, which decrease the passivation currents to acceptable values (up to 100 A per object): passivation with continuous filling of the object, passivation in a less aggressive solution, passivation after the prior chemical passivation of the surface.

Passivation with continuous filling is a common procedure used in the start-up mode. Problems relating to the passivation with continuous filling deal with the placing of a cathode, because AP can work properly only if at least partly immersed, which happens, for example, in vertical cylindrical vessels, only after the entire bottom is covered; high currents are needed then for passivation. The solution is based on the modification of the vessel's bottom to a conical one or a spherical one with a pit where the end of the electrode encroaches.

Continuous filling is often combined with the reduction of the operation environment aggressiveness. The reduction of aggressiveness can be achieved by a drop of temperature, change of concentration of the aggressive element, change of hydrodynamic conditions, or addition of passivating substances. Environment parameters (temperature, concentration, flowing rate) are continuously modified during the start-up mode to correspond to the values of operation without draining the equipment content.

The reduction of temperature is important, particularly for equipment operating under elevated temperatures. This procedure is very effective, since the dependence between passivation current and temperature is exponential. Temperature reduction

can eventually result in self-passivability of the metallic material.

In the start-up mode, metallic surface can be passivated by direct current without any automatic regulation of potential. The reference electrode then has a controlling function only. The power supply is controlled manually according to the potential of the passivated device.

It is not advisable to apply automatically controlled start-up mode for equipment operating continuously. It only makes sense with discontinuous productions with periodical passivation cycles.

To reduce the needs for passivation current, it is also advisable to place the cathode asymmetrically in the vicinity of the protected surface. The nearest place to the cathode passivates at first, and the rest of the surface follows. If required by conditions, auxiliary cathodes must be used, for example, for passivation of a storage vessel bottom, since the current needs to identify the minimum surface of the cathode.

Time of the start-up mode depends on the corrosion environment aggressiveness against the specific metallic material and on the source power used for the operation mode, which the protected equipment will be migrated to. The start-up mode takes hours, at the maximum, tens of hours.

The time of the actual passivation is relatively short, but the stabilization of the passive current is slow. It is necessary to wait until the current on the filled equipment drops, under the operation conditions, below the maximum output values of the automatically regulated source. During the start-up mode of AP of complicated equipment, requirements given by the protection throwing power must be taken into consideration, and the appropriate start-up mode procedure must be selected accordingly.

#### 4.24.5.2 Operation Modes

Once the start-up mode, which usually consists in a one-off action, is over, the protected object is reconnected to regulating circuits that ensure permanent protection process. The methods of polarization that might be used to ensure operation modes of AP can be divided into types continuous, discontinuous, and combined.

##### 4.24.5.2.1 Potentiostatic polarization

Polarization is referred to as potentiostatic if the potential of the protected surface is maintained on the specific value by direct current. This type of

polarization uses a three-electrode connection (protected object, cathode, reference electrode) where the potential difference between the protected surface and the reference electrode is permanently compared to the voltage corresponding to the required value of protection potential, and the differences are compensated by the current passing between the protected surface and the cathode. A regulator that ensures this joint regulation of the protected surface potential is called a potentiostat.

The protected object must be connected to the regulator by two wires (measuring and power), because the voltage, which is added to the value of the actual potential of the equipment, drops in the protected object power supply during the current passage. In operation, the regulating and power parts of the potentiostat are sometimes divided in two devices and the power part is usually placed close to the protected object.

For potentiostatic polarization, potential is the optional quantity and protection current is the depending quantity.

#### **4.24.5.2.2 Polarization under constant terminal voltage**

Polarization under constant voltage used to be common for cathodic protection, but for AP, it is useful only if the corrosion systems lack transpassivity. This procedure can be used in practice for the AP of titanium in the sulfuric acid environment. The anodic polarization from a DC source was also proposed as a method of reduction of carbon steel corrosion in liquid fertilizer containing ammonium nitrate in Lawrence's and Eagle's patents<sup>2</sup> from 1945, which is the first documented proposal of the AP. In addition to the AP of titanium, at present, the polarization under constant terminal voltage is important, especially for starting and emergency modes.

#### **4.24.5.2.3 Periodic polarization**

Periodic polarization by direct current is a method that brings certain simplifications to the AP. Similarly, to the potentiostatic polarization, the connection is effected through three electrodes (four wires). It applies the principle that the potential of an anodically protected metal, once the polarization current is switched off, shifts automatically to the negative direction. As soon as the lower potential threshold is reached, the current is switched on again in the preset value. It passes through the circuit as long as the protected surface potential achieves the upper threshold of the required potential interval. The

periodical switching of the current in the cathode-protected surface circuit is ensured by the regulator controlled by the potential balance between the reference electrode and the protected surface.

Periodical polarization offers a lot of advantages, because it does not require the construction of power potentiostats and the source powers can be easily changed according to the size of the protected object. The periodical polarization has been used since the beginning of a wider industrial application of AP; nevertheless, nowadays it is being left for potentiostatic polarization.

#### **4.24.5.3 Emergency Modes, Failures, and Maintenance of AP System**

The AP requires a reliable regulation of the protected surface potential within a given potential interval, outside of which very intensive corrosion occurs. To avoid such corrosion under both threshold operation conditions and the main regulating circuit outage, it is essential to establish an emergency mode, regular controlling, and maintenance of the entire anodically protected device. To properly select the emergency mode, which includes not only the polarization method but also all restoration measures, we have to consider all causes of the emergency.

To make the emergency mode ensure proper protection against the consequences of failures, it must be complemented with regular preventive checkups and have the protected equipment maintained by qualified personnel. Reference electrodes (testing by an independent electrode), the resistance of conductors, operation of regulators, sources, signalization, and the state of corrosion attack of critical places of the protected object should be subjected to regular checkups as well.

Maintenance should consist in timely replacement of those AP system parts that show signs of lower reliability, for example, the reference electrode when the potential oscillates outside the permitted interval. It is also essential to renew those parts that get worn by the operation, for example, electrodes and joints in the circuit.

The basic requirement for a reliable operation of AP is a timely signalization that alerts the personnel that the conditions of the operation mode are no longer complied with. The signalization can be complemented with an automatic action that decreases the aggressiveness of the corrosion environment (e.g., temperature

reduction). The signalization should mean that the equipment operates in an emergency mode or that the emergency mode is needed. Failures that do not directly jeopardize the reliability of the operation and are thus not a reason for transition to the emergency mode should not be connected to this signalization; they should be removed by regular maintenance.

The emergency mode should ensure the operation of the AP system for a period of time necessary to remove the failure or to finish the production operation so as to avoid any production losses. After transition to the emergency mode, the personnel must distinguish the level of urgency, since some states may mean that even the emergency mode cannot prevent vast corrosion – in such a case, the equipment must be immediately shut down. Usually the operation can continue for several, even, tens of hours in the emergency mode. However, it is not advisable to opt for emergency modes that ensure long-term operation, because the personnel is thus not forced to promptly remove the failure that caused the transition from the operation mode to the emergency mode.

Since the AP-suitable corrosion systems' time to spontaneous activation must be at least 10–15 min (1 h is better), short-time source outage should not matter.

To enhance operation safety, back-up elements of the AP system are usually installed on the protected equipment. It concerns especially the reference electrodes that are installed in the minimum number of three – the operating one and the other two as back-up or controlling ones. The difference (higher than permitted) between the operating and back-up electrode usually causes the transition to the emergency mode. The installation of more reference electrodes also enables simple identification of the defective electrode and the exchange of the operating electrode. The back-up regulating circuit is also available, which consists of an independent regulator (or a source) and a back-up reference electrode. Therefore, it is possible to connect two potentiostats in parallel (**Figure 3**), and a periodic regulator in parallel to a potentiostat.

The transition from the operation mode to the emergency mode should be automatic.

Operation guidelines must be provided to each AP installation. It should solve specific problems of the equipment and give unambiguous directions for the personnel regarding controlling and maintenance as well as the identification of failures.

At present, AP systems are computerized. The computer records the operation parameters of the protected equipment. It enables the personnel to

**Figure 3** Main and back-up sources (potentiostats) for six anodically protected objects.

identify the cause of a failure and define the process of restoration to the normal state.

#### 4.24.5.4 AP by Protectors

The source of current maintaining the potential of the protected surface in a passive range can be, in principle, formed directly in the protected equipment, if connected with a cathodic material (protector) in which reduction reactions proceed spontaneously. The AP by protectors is based on the principle of passivation by connection to cathodic materials. These requirements can be complied with by materials that can be divided into sacrificed and inert ones.

The sacrificed materials include oxide protectors composed of metal oxides that release electrons when dissolved in a corrosion environment, in particular, oxides of iron ( $\text{Fe}_2\text{O}_3$ ) and manganese ( $\text{MnO}_2$ ). Oxide protectors can be considered analogous to sacrificed anodes of cathodic protection, since they provide the necessary current by its dissolution, but of the opposite polarity.

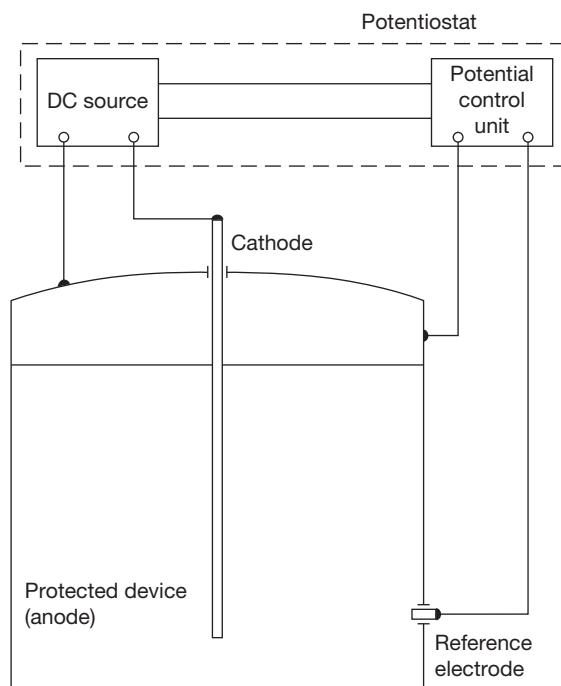

Most of other materials that could be used as protectors provide the essential current by a reduction reaction of the solution components. It is given by the fact that cathodic reactions proceed on the surface of the protector (Pt, graphite) with lower overvoltage than on a passive metal.

Titanium is the best material for AP by protector, because it usually has a low passive current density and the passivation potential is substantially negative.

Protectors are not used in practice, since oxide protectors are consumed by spontaneous dissolution and must be thus frequently replaced or supplemented. Moreover, we cannot be satisfied with the existing fixation of protectors, because they have insufficient contact with the inside of the protected equipment. Inert protectors lose their activity continuously and their surface must be retreated by anodic polarization.

#### 4.24.6 Elements of the AP System

The AP system consists of a protected object, cathodes, reference electrodes, and electric equipment (a regulated source of direct current and connection cables) (Figure 4).

**Figure 4** Diagram of anodically protected apparatus.

#### 4.24.6.1 Cathodes

The passage of current polarizing an anodically protected metallic surface is ensured by an auxiliary electrode connected to a negative pole of the direct current source. During the passage of direct current, a reduction reaction of environment components proceeds at the cathode and the cathode partly corrodes. The distribution of the current on the protected surface must be ensured by a suitable construction of the cathode, and corrosion resistance of the cathode must be ensured by selecting a suitable material, protection mode, and the construction as well. The cathode material must have a sufficient service life. It must be recognized for its suitable mechanical properties, good electric conductivity, low cathodic reaction overvoltage, and an acceptable price. During the cathode polarization, it is theoretically possible to achieve a state of immunity where no corrosion occurs. This, however, requires very high current density, which, considering the uniform distribution of the protection current, is undesirable. High current densities can cause problems with the formation of nonconductive deposits or hydrogen entry in a metal. It is thus much more common to use the cathode under conditions of suppressed

anodic dissolution, along with the continuous polarization. The cathode construction depends, in particular, on the construction of the protected equipment. The requirement to have cathodes usable for both passivation by current in the start-up mode and the operation mode is unrealistic in many cases, because it depends on the specific corrosion system (passivation currents, environment conductivity) and on the technology regime applied within the protected equipment (batch, continuous, liquid-level fluctuation). The necessity to construct cathodes for operation modes, while considering the throwing power, is overrated, given high conductivity of electrolytes applied successfully for AP. The throwing power of AP is very high on passive equipment. Given that the conductivity of corrosion environments suitable for AP often exceeds  $10 \text{ S m}^{-1}$  and the current densities do not achieve  $0.1 \text{ A m}^{-2}$ , there is no essential difference, for example, for sulfuric acid coolers, between polarization of surface in the distance of 1 mm and meters from the cathode. The main ohmic resistance in the system is exerted by the passive layer. The smallest distance between the cathode and the protected surface is given by the risk of a galvanic contact at operation vibrations of the protected equipment, and the greatest distance is given by the acceptable deviation from the protection potential, which can rise in many cases up to 100 mV.

Different types of stainless steels, nickel alloys, nickel, carbon steel, silicon casts iron, graphite, lead, copper, platinum, platinum plated metals, tungsten, and others are materials used for cathodes, depending on the corrosion environment.

In case of the most frequent applications of AP on sulfuric acid coolers, cathodes are usually placed in parallel to the exchanger axis. Even the cathodes placed transversally through an unbound bundle of pipes proved to be very successful (Figure 5). The advantage of this solution is that short weld-free cathodes can be used. The length of cathodes equals the exchanger's outside diameter plus the allowance for sealing and electric contact.

Another advantage of the transversal arrangement is that it is necessary to seal only the opening for a cathode at the outside shell. With this arrangement, it is possible to refit the sealing during operation without any risk of acid leakage to the cooling water in case of sealing failure. This construction solution also eliminates intensified corrosion of cathodes going through baffle plates. Practical experience shows that the service life of cathodes made of common austenitic steel at temperatures of acid up to  $90^\circ\text{C}$  is  $\sim 3$  years and

**Figure 5** Horizontal shell and tube coolers with spacing of tube bank. Rod stainless steel cathodes are placed transversally through an unbound bundle of pipes.

they are simply replaceable. Cathodes made of nickel alloys are recommendable for higher temperatures and lower concentrations of acid.

In vertical storage vessels, it is advisable to use cathodes in the vessel axis so as to avoid galvanic contact with the bottom, however, to secure operation even with the minimum volume of liquid in the vessel.

The size, number, and location of cathodes are individual according to the type of the protected object. The potential distribution over the protected surface is approximately calculated according to mathematical relations derived for different regimes.<sup>17–23</sup> Nevertheless, it must be taken into consideration that, in case of the industrial AP applications that stood up the competition of other anticorrosion measures, the protected surface predominantly passivates spontaneously and the conditions of current distribution at passivation thus do not have to be addressed.

#### 4.24.6.2 Reference Electrodes

To make the AP system work well, it is necessary to keep the potential of the entire protected surface within the potential passivity range where corrosion rate is technically acceptable. The reference electrode, which is contained as a permanent part in all existing AP systems, acts as a potential measurement sensor. Bad function of a reference electrode can cause critical damage to the protected equipment, that is why reliable types of electrodes are used and more electrodes are placed in an angle piece of protected equipment. Electrodes act as sensors, which the direct current source is attached to as well as sensors for back-up and controlling systems. The reference electrodes

must prove to be stable enough under operation, and to have a minimum service life of 1 year. Bad function of a reference electrode may cause that a potential of the protected equipment lies outside the required passive range. Any shift to both positive and negative directions may lead to the growth of corrosion rate – in some cases, by several orders of magnitude, the consequence of which is damage of the equipment.

Any electrode that is difficult to polarize and the potential of which does not significantly change in time or in environment may serve as a reference electrode to measure potential in an electrolytically conductive environment. The requirement of the operating reference electrode potential oscillation by  $\pm 30$  mV suffices for most anodically protected equipments.

In practice, reference electrodes are loaded with current that corresponds to the input resistance of a potential controller and the potential difference between the reference electrode and protected equipment. Polarizability of a reference electrode can be decreased by increasing its electrochemically active surface. Change of the electrode potential in time is given by the fluctuation of temperature and composition of the electrolyte solution. Temperature dependence of the potential of most reference electrodes can be disregarded to the extent of minor fluctuation of operation temperatures.

Electrodes that can be used as reference electrodes are generally distinguished to electrodes of the first and the second kind. On electrodes of the first kind, the reaction of charge transfer proceeds directly between the electrolyte components or between the electrode and an electrolyte component. Electrodes of the second kind exchange the charge through an insoluble salt or oxide.

The existence of equilibrium is supposed for the said kinds of electrodes, but the electrochemical protection may work even with reference electrodes that are in a stationary state in which mixed potential is established. These are electrodes upon which corrosion or metal deposition proceeds spontaneously, or electrodes to which the potential is enforced by a passage of direct current.

The majority of reference electrodes used or usable for AP belong to electrodes of the second kind, such as calomel electrode, silver chloride electrode, and mercury sulfate electrode for sulfuric acid environments, and mercury oxide electrode for alkaline environments (**Figure 6**).

The equilibrium on oxide electrodes of all kinds is affected by the concentration of  $\text{OH}^-$  or  $\text{H}^+$  ions, that is, by the pH of the solution. The advantage

**Figure 6** Reference electrodes filled with working medium are used for sulfuric acid and sodium hydroxide applications.

of these electrodes is that they can be used (except for the mercury oxide electrode) directly in the corrosion environment without the necessity to separate electrolyte. The disadvantage is that they have a lower potential reproducibility, which is given by the effect of other oxidation–reduction reactions of the corrosion environment components. A number of oxidized metals were tested for AP in terms of their use as a reference electrode. Pt, Au, Rh, Ir, Hg, Sb, and Mo oxide electrodes are used preferentially.

A nickel electrode in the environment of electrodeless nickel bath is one of the nonequilibrium electrodes upon which a stationary reaction proceeds and which can be used as a reference electrode. The electrodes that maintain their potential as a consequence of a corrosion reaction include, for example, bismuth in liquid fertilizers containing ammonium nitrate, carbon steel, and lead in the solution of ammonium hydrogencarbonate, and silicon cast iron in hot concentrated sulfuric acid. Also, other metals can be used in the environment where the acceptable corrosion rate below  $1 \text{ mm year}^{-1}$  secures sufficient potential stability along with the acceptable service life of the electrode. This type of electrode can be used only if there is no risk that the electrode suddenly turns from the active to the passive state and vice versa. Metal depositions must be regularly removed from the surface of nonequilibrium electrodes and corroding electrodes must be replaced with new ones. The overview of reference electrodes used in operation is given in **Table 1**.

Construction solution of the reference electrode or the whole potential sensor is applied according to the specific type of equipment and conditions given by the corrosion environment. With the potential sensor, we understand not only the electrode itself, comprising the filling and the electrode casing, but

**Table 1** Reference electrodes for industrial anodic protection

<i>Electrode</i>	<i>Environment</i>
Calomel (Hg/Hg <sub>2</sub> Cl <sub>2</sub> )	Sulfuric acid Ammonium nitrate–urea Alkaline solutions Universal
Mercurousulfate (Hg/Hg <sub>2</sub> SO <sub>4</sub> )	Sulfuric acid Hydroxylammoniumsulfate
Silver chloride (Ag/AgCl)	Sulfuric acid Ammonium nitrate–urea Universal
Silver sulfide (Ag/Ag <sub>2</sub> S)	Kraft liquor
Platinum Pt/PtO <sub>2</sub>	Sulfuric acid Phosphoric acid Mixed fertilizers
Gold (Au/Au <sub>2</sub> O)	Sulfuric acid Phosphoric acid

Wolfram (W/WO <sub>3</sub> )	Sulfuric acid
Graphite	Ammonia environment Ammonium nitrate–urea

also fittings for the electrode installation and connection to the regulating circuit.

Reference electrodes are distinguished to immersing, level, pressure, and external electrodes according to how they are attached to the equipment. Pressure electrodes are most frequently used in completely filled equipment and below the liquid level in pressure-free equipment. The advantage is that the electrode–circuit connection and the shielded wires are located outside the aggressive environment. On the other hand, the necessity to have reliable pressure plugs and the impossibility to replace electrodes without the equipment shut-down are disadvantageous. These electrodes should be able to operate in all positions.

A reference electrode is located in a place with a permanent electrolytical connection with the protected surface close to that surface. The best thing is to place the operating reference electrode close to

the surface that is the least accessible for current from the cathode, or in places with critical temperatures or concentrations.

#### 4.24.6.3 Electric Equipment

Direct current sources that are connected with conductors to the AP system components and the protected equipment are used in AP to polarize the protected surface to the potential within the passivity range. Other complementary electric devices are connected to control the operation and enhance reliability. The connection and the function of the AP electric devices vary according to the selected modes. Considering the technological development, many connections publicized in literature can be assumed as outdated.

A power-supplied rectifier is usually the source of direct current for AP. For AP, the final rectified voltage does not have to show low oscillation, since it was detected that filtration has no effect on the protection effectiveness. Automatically controlled sources operating in the mode of potentiostatic polarization are used the most frequently for AP ([Figure 3](#)).

The installed output per one AP unit mostly does not exceed 5 kW. The energetic needs of the AP system are negligible, the operational requirements for current are below 0.1 A m<sup>-2</sup> (mostly <10 A), when the supply voltage is lower than 10 V. The price of the regulation device does not depend on the size of the protected object.

The automatic compensation of ohmic drop is desirable under operation conditions only in environments with low specific conductivity approximating 1 S m<sup>-1</sup>. If the reference electrode is placed in the vicinity of the protected surface, the ohmic drop is mostly not remarkable.

Some operation electric devices used for AP of objects with fluctuating liquid level have additional circuits that switch off the AP system automatically after emersion of the operating reference electrode, or cathode.

Cabling, with which the protected equipment, cathodes, and reference electrodes are interconnected with the source, regulator, and controlling devices, can be distinguished to power and measuring. Power cabling supplies the protection current to the protected equipment–source–cathode circuit and it must be rated to the values required by AP of the specific object.

The perspective development of electric devices used for AP is seen in the field of digital

technologies. Controlling and operation will be secured by a computer or a microprocessor. Operation data of both the AP system and the protected equipment are continuously recorded and make it thus possible to identify the causes of potential deviations from the operation mode of the AP system.

#### 4.24.7 Environments Suitable for AP

AP is used with passivable metals in electrolyte, having a sufficient width of a stable passive range (minimum 300 mV) and a low corrosion rate (usually  $<0.1 \text{ mm year}^{-1}$ ), where localized forms of corrosion do not occur at the protection potential. The minimum environmental erosion incidence and stable chemical composition are other important factors. Moreover, the environment must not be decomposed at the protection potential. The time to activation, after the polarization current is switched off, must be also sufficiently long (minimum 15–30 min).

Most literature data on metal passivation in aggressive environments are based on the results of laboratory experiments performed under conditions very difficult to be compared. This chapter summarizes, in general, the literature data in order to identify, considering significant corrosion systems, important parameters of optimal protection, and location of iso-corrosion lines (curves connecting conditions under which the rate of uniform corrosion achieves a given level) in the concentration–corrosion environment temperature graphs. The objective assessment is complicated by different testing times, different levels of corrosion environment pollution, and the dependence of the optimal protection potential on concentration and temperature of the corrosion environment.

Corrosion diagrams shown in this Chapter must be treated as orientation diagrams displaying zones with corrosion rate below  $0.1 \text{ mm year}^{-1}$  with or without AP. Zones with corrosion rate below  $0.1 \text{ mm year}^{-1}$  under AP are distinguished in two parts. In the first part, there is a high probability that the corrosion rate will dwell below this threshold, in the other so-called indefinite zone, the probability is  $\sim 50\%$ .

In addition to corrosion rates, potential and current levels, another parameter vital for the AP is the corrosion environment conductivity. The conductivity acts as the decisive factor of the AP feasibility, it affects the throwing power, essential voltage of a direct current source, construction of a cathode, and the location of a reference electrode.

The conductivity of electrolytes changes within wide thresholds, depending on the composition, concentration, and temperature. Specific conductivity  $\gamma$  ( $\text{S m}^{-1}$ ), that is, the reciprocal value of resistivity  $\rho$  ( $\Omega \text{ m}$ ), is very important for AP. The concentration dependence of specific conductivity ( $\gamma$ ) for some strong electrolytes at  $25^\circ\text{C}$  is shown in **Figure 7**.

If the specific conductivity exceeds  $10 \text{ S m}^{-1}$ , no special measures are essential to be taken to ensure uniform distribution of current on the protected passivated surface, except for cases when the surface is shadowed (e.g., in crevices or in narrow pipes).

With specific conductivity ranging from 1 to  $10 \text{ S m}^{-1}$ , the AP is feasible, if more cathodes are used and their surface is located in approximately the same distance from all parts of the protected surface.

With specific conductivity below  $1 \text{ S m}^{-1}$ , the electrolyte resistance in a usual construction arrangement is comparable with the resistance exerted by the passive layer during the current passage. Even the voltage of a source relates, in particular, to the resistance of electrolyte between a cathode and an anode and rises up to tens of volts. After that, it is impossible to ensure a uniform distribution of protective current. The need for power supply grows and the safe source voltage is exceeded. Therefore, AP is not recommendable for specific conductivity below  $1 \text{ S m}^{-1}$ . Specific conductivity of electrolytes grows along with the temperature by 2% to 1 K.

**Figure 7** Concentration dependence of specific conductivity ( $\gamma$ ) on various strong electrolytes at  $25^\circ\text{C}$ .

#### 4.24.7.1 Sulfuric Acid

A good deal of literature references deal with this environment, because it belongs among the most widespread in industrial conditions. Specific conductivity of sulfuric acid solutions with concentration of 2–96% exceeds  $10 \text{ S m}^{-1}$  under normal temperature. For concentrations above 96%, the specific conductivity decreases and hits the minimum at the concentration of 99.75% ( $0.8 \text{ S m}^{-1}$ ). Then it grows again and the oleum under normal temperature can reach a specific conductivity of  $5 \text{ S m}^{-1}$ .

##### 4.24.7.1.1 Carbon steel and cast iron

Technically acceptable corrosion rate of unprotected carbon steel can be allowed for only in an acid with a concentration over 70% at temperatures not exceeding  $20\text{--}25^\circ\text{C}$ . Moreover, the corrosion resistance of steel remarkably drops with the motion of the corrosion environment. Carbon steel behavior in sulfuric acid during anodic polarization was observed under laboratory conditions by many authors within the entire concentration interval and also at elevated temperatures.

The potential–current polarization curves for carbon steels in sulfuric acid solutions can be divided into three types, characterizing a specific concentration interval. For low concentrations to those of 60 or 65%, the polarization curve of carbon steel in the sulfuric acid environment has a shape characterized by curve 1 in **Figure 8**. On the curve above the corrosion potential, there is a very wide range of activity with high currents. Passivation can be observed within a wide range of potentials where the current considerably oscillates. The passive range is limited by a transpassivation potential at which oxygen starts to evolve. Curve 2 in **Figure 8** is characteristic of steel in acid with a concentration of 65–77%. The activity starts to be less significant and a second maximum appears in the passive range, and is followed by a range of low passive currents as far as the transpassivation potential, at which oxygen starts to evolve (similar to the previous case). Both curve 1 and curve 2 are the curves of the type-I in **Figure 2(a)**. The third type of a curve is typical for steel in acid with concentration beyond 78%, including oleum. The initial progress is analogous to curve 2, that is, insignificant or no activity (curves of type-II or III in **Figure 2(b) and 2(c)**), the passive range is not limited by the transpassivation potential (up to  $4 \text{ V(SHE)}$ ).

Sulfuric acid with a concentration up to 60% is noted for extremely high passivation current densities

**Figure 8** Potentiodynamic curves of mild steel in sulfuric acid at  $25^\circ\text{C}$ . 1–25%, 2–70%, 3–90%.

**Figure 9** Dependence of mild steel passivation current density ( $i_{cc}$ ) on the sulfuric acid concentration (wt%) at ambient temperature.

$i_{cc}$  (asi  $10^3 \text{ A m}^{-2}$ ) (**Figure 9**) and high current densities in a passive range  $i_p$  (**Figure 10**) even at normal temperatures. The time to activation is usually very short, once the polarization is switched off.

The use of AP is feasible only for concentrations over 70% where active range practically vanishes, since the steel shows a better tendency to spontaneous passivation.  $i_{cc}$  values drop exponentially with time to  $1\text{--}10 \text{ A m}^{-2}$  and even the passive current densities reduce significantly (below  $0.1 \text{ A m}^{-2}$ ).

**Figure 10** Dependence of mild steel passive current density ( $i_p$ ) on the sulfuric acid concentration (wt%) at ambient temperature.

Carbon steel behavior, depending on the acid concentrations, markedly changes according to the composition and higher stability of the forming passive layer. Within the range of potentials from 0 to 0.7 V, the steel resistance is based only on the layers composed of iron compounds in the oxidation state II; the stability of these layer is rather small in acid with concentrations up to 70%. At higher concentrations, the solubility of ferrous sulfate in acid diminishes. At higher potentials (over 0.7 V(SHE)), we can observe oxidation of compounds in the oxidation state II and formation of an oxide layer with iron in the oxidation state III, which is relatively resistant within the whole interval of acid concentrations. Beside the oxide layer, it is the ferric sulfate layer that applies at higher acid concentrations (over 70–80%).

The oxidation of  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  in compounds forming the protective layer leads to the second maximum on potentiodynamically obtained potential–current curves (curves 2 and 3 in [Figure 8](#)). The steel is passive practically from the potential of 0.2 V(SHE) and the second maximum has nothing to do with activity of the steel. It also explains the great influence of flow on the corrosion of anodically protected steel. The flow aggravates the passivation process within the whole concentration interval by eroding the primary salt layer that precedes the formation of the oxide layer.

Concentration dependencies of characteristic current densities  $i_{cc}$ ,  $i_p$  and the potential  $E_p$ ,  $E_t$  are depicted

**Figure 11** Dependence of mild steel passive range on the sulfuric acid concentration (wt%) at ambient temperature (close hatching – potential range suitable for AP).

in [Figures 9–11](#). The scattering of current values in [Figures 9 and 10](#) is caused by different methodology and different hydrodynamic testing conditions.

Passivation current density ( $i_{cc}$ ) values ([Figure 9](#)) lying within a concentration range over 70% depend, a lot, on time and are low, since the salt layer of ferrous sulfate forms spontaneously on the surface, and so it is disputable whether the notion ‘passivation current density’ is used correctly.

The dependence of a passive current density  $i_p$  on concentration is more complicated. Even the optimal protection potential within the sulfate layer ( $\text{Fe}^{2+}$ ) depends on the acid concentration, and therefore, there are big discrepancies in the results presented by different authors. The relatively highest  $i_p$  and thus the corrosion rate values range within the interval of 75–100% for 95%  $\text{H}_2\text{SO}_4$ , minimum  $i_p$  and corrosion values can be observed at 80–90% and at 98–99%. The flow of acid can easily increase both the passive current and corrosion two to five times, and in the stability range of the sulfate layer ( $\text{Fe}^{2+}$ ), even ten times.

At concentrations up to 60%, the passive range ([Figure 11](#)) is limited by potentials of 0.7 and 1.9 V; with the increase of acid concentration, it expands to both the negative side (the range of salt passivity of ferrous sulfate) and the positive side, because the overvoltage of oxygen evolution reaction is growing. With concentrations above 78%, oxygen does not evolve even at 4 V(SHE). Hatching of the range of

potentials suitable for AP is more dense and lies within 1.0 and 1.8 V(SHE). At higher concentrations ( $\sim 96\%$ ), the best resistance is achieved within the potential range of 0.9–1.2 V(SHE).

Corrosion resistance data of the anodically protected carbon steel are generalized in a corrosion graph (Figure 12). The graph makes it obvious that if we need to have the corrosion rate below  $0.1 \text{ mm year}^{-1}$ , we can use carbon steel only at high concentrations of sulfuric acid and up to temperatures of  $\sim 40\text{--}50^\circ\text{C}$ . The zone of probability defines the aggressiveness maximum within the exploitable concentration interval (at 95% concentration).

Since the unprotected steel, due to its low price, can be used to a limited extent even at temperatures when AP is effective, it makes sense to compare corrosion rates with and without protection. This proportion depends very much on concentration, temperature, and probably, also the flow. Mostly it varies between 10 and 100.

Results of tests of carbon steel AP were applied in operation conditions of storage of both pure concentrated sulfuric acid and oleum.

#### 4.24.7.1.2 Stainless steels and alloys

Stainless steels and alloys on iron, chromium, and nickel basis are the fundamental construction material for heavily aggressive environments where AP can be applied. The properties of stainless steels can be modified by alloying, which gave rise to a number of types of stainless steels. The FeCr18Ni10(Mo) austenitic steels are of the greatest importance. Highly alloyed steels and alloys used for the construction of chemical plants are usually materials with sufficient resistance to corrosion, and mostly, it is not necessary to protect them anodically. AP allows their replacement by less costly chromium–nickel stainless steels.

Unprotected FeCr18Ni10 steels in sulfuric acid solutions have corrosion rate below  $0.1 \text{ mm year}^{-1}$  at normal temperature with concentration intervals below 10% and over 78%; FeCr18Ni10Mo steels below 20% and over 75%. The resistance drops with increasing temperature and at  $50^\circ\text{C}$ , the FeCr18Ni10 unprotected steels can only be used at concentrations below 2%; the FeCr18Ni10Mo steel below 10% and over 90%. At temperatures over  $70^\circ\text{C}$ , unprotected steels of this type are inapplicable in sulfuric acid up to 99% (Figure 13).

Corrosion resistance of chrome–nickel stainless steels largely depends on the content of oxidizing substances (e.g., oxygen, ferric ions) and the presence

**Figure 12** Range of corrosion rates below  $0.1 \text{ mm year}^{-1}$  for mild steel in sulfuric acid (closest hatching – without AP, thin hatching – with AP).

of activating substances (e.g., chloride ions) in the solution. Localized forms of corrosion (e.g., pitting, intergranular, corrosion cracking) can occur, depending on the composition and structure of the metal as well as on the presence of other substances in the sulfuric acid solution and its temperature.

The potential–current polarization curves for chromium–nickel austenitic steels have a typical shape at concentrations up to 80% (Type-I in Figure 2(a)), where significant activity is followed by a passive range limited by the transpassivation potential, above which the metal dissolves and oxygen evolves.

At a concentration over 80%, the activity range is gradually suppressed, the passive range is interrupted with a significant maximum at  $\sim 1.7 \text{ V}$ , beyond which there is a range of low currents. For concentrations exceeding 93%, the drop of current is permanent (to  $4 \text{ V(SHE)}$ ), for concentrations from 80% to 93%, it grows again in the range above  $2.3 \text{ V(SHE)}$ .

Although the passive layer is formed exclusively by oxides in the range of concentrations up to 80%, the sulfate layer applies even at higher concentrations and mitigates the oxygen evolution and anodic dissolution.

The passive range is determined by the passivation and transpassivation potential, see Figure 14. In fact, the passive range at higher potentials (over  $1.5 \text{ V(SHE)}$ ) has no importance for AP. The potential range of the stable passivity is almost independent of the temperature; with the growth of acid concentration, the passivation and transpassivation potential slightly shifts to more positive values. The optimum

**Figure 13** Range of corrosion rates below  $0.1 \text{ mm year}^{-1}$  for stainless steel FeCr18Ni10(Ti) in sulfuric acid (closest hatching – without AP, thin hatching – with AP). 1 – isoline  $0.1 \text{ mm year}^{-1}$  for FeCr18Ni10Mo without AP, 2 – isoline  $0.1 \text{ mm year}^{-1}$  for FeCr18Ni10Mo with AP.

**Figure 14** Dependence of stainless steel (FeCr18Ni10(Mo)) passive range on the sulfuric acid concentration (w (wt%)) at ambient temperature (closest hatching – potential range suitable for AP).

protection potential lies within 0.55 and 0.75 V(SHE) for concentrations up to 80%. At higher concentrations, the optimum potential shifts in a positive direction up to  $\sim 1 \text{ V(SHE)}$  for 98% acid.

The values of passivation current density are concentration and temperature wise strongly dependent (Figure 15). The scattering of values in Figure 15

**Figure 15** Dependence of passivation current density ( $i_{cc}$ ) of stainless steel FeCr18Ni10(Mo) on the sulfuric acid concentration (wt%) at 20 and  $90^\circ \text{C}$ .

is given, on the one hand, by the fact that the graph summarizes data for austenitic steels of various types, and on the other hand, by various experimental conditions. The growth of passivation current values  $i_{cc}$  along with the acid concentration is reported to be steep up to  $\sim 50\%$ , which is followed by a drop, and steels in acid with concentrations higher than 70% at  $20^\circ \text{C}$  or 85% at  $90^\circ \text{C}$  are, according to other conditions, self-passivable. Spontaneous passivation also occurs at low concentrations of sulfuric acid.

Passive current densities grow more substantially with the concentration growth up to 20%. A steep drop follows after a flat maximum at 50–60%.

At  $20^\circ \text{C}$ , the values  $i_p$  are stable within the whole concentration interval below  $0.02 \text{ A m}^{-2}$ ; at  $50^\circ \text{C}$ , below  $0.1 \text{ A m}^{-2}$ . The sulfuric acid concentration–temperature diagram with isolines of corrosion rate of  $0.1 \text{ mm year}^{-1}$  is shown in Figure 13 for stainless steels of the FeCr18Ni10(Mo) type.

According to these data, AP extends the range of use of stainless steels of the FeCr18Ni10 type to the whole concentration interval of sulfuric acid solutions up to the temperature of  $60^\circ \text{C}$  (for steels of the FeCr18Ni10Mo type up to  $75^\circ \text{C}$ ).

Corrosion rate with AP is technically acceptable up to  $100^\circ \text{C}$  for concentrations lower than 20% and higher than 95%. For high concentrations, the maximum at corrosion rate isolines is achieved at  $\sim 78\%$  and the growth after the minimum at 93% is steep; at concentrations of  $\sim 98\%$ , sufficient resistance can be allowed for even at temperatures substantially

exceeding 100 °C, if there is a minimum content of iron. The resistance of steels containing molybdenum is higher within the range of concentrations below 75%.

At concentrations below 80%, the potential–current polarization curves for chromium–nickel austenitic steels have a shape corresponding to the type-I (**Figure 2(a)**). The range of significant activity is followed by a passive range limited by the transpassivation potential, above which the metal dissolves and oxygen evolves.

At concentrations over 80%, the curve has a shape of either Type-I, II, or III according to the temperature and iron content (**Figure 2(a)–(c)**). The range of activity is gradually suppressed, the passive range is interrupted with a significant maximum at  $\sim 1.7$  V, beyond which there is a range of low currents. For concentrations exceeding 93%, the drop of current is permanent (to 4 V(SHE)); for concentrations from 80 to 93%, it grows again in the range above 2.3 V(SHE). Although the passive layer is formed exclusively by oxides in the range of concentrations up to 80%, the sulfate layer applies even at higher concentrations and mitigates the oxygen evolution and anodic dissolution.

To achieve effective AP, the minimum concentration of iron ions in flowing sulfuric acid at 100 °C must be 7 ppm (solubility of ferric sulfate). The stability of the passive sulfate layer during acid flow is conditioned by the origination of trivalent iron compounds whose solubility in concentrated acid is, by approximately two orders, lower than that of bivalent iron compounds. Spontaneous passivation results in the formation of  $\text{Fe}^{2+}$  sulfate passive layer, while anodic polarization above 0.85 V(SHE) leads to the formation of  $\text{Fe}^{3+}$  sulfates. This is the reason why cooling systems with AP do not need any significant limitations of acid flow rate and why erosion corrosion does not occur in them, in contrast to systems without AP.

Austenitic stainless steel in hot concentrated acid has a curve with the shape of type-I (free corrosion potential in activity only) (**Figure 2(a)**) merely in pure acid, while in acid with increasing iron content, the shape is of a type-II (two free corrosion potentials) (**Figure 2(b)**), exceeding 7 ppm Fe type-III (free corrosion potential in passivity only) (**Figure 2(c)**).

In hot concentrated sulfuric acid, we can observe a spontaneous oscillation of free corrosion potential between the active and passive state. The oscillations are caused by reversible changes in the exchange current relating to the cathodic reduction of sulfuric

acid, depending on the presence or absence of nickel sulfide on the steel surface.

Moreover, AP increases corrosion resistance of chromium and high-alloyed steels. Their curve of concentration dependencies of characteristic current densities  $i_{cc}$ ,  $i_p$  is identical, in terms of quality, with that of chromium–nickel steels. Values of optimal protection potentials are also approximately the same. Temperature dependence of currents typical for stainless steels can be predominantly expressed by the value of activation energy 60–80 kJ mol<sup>−1</sup>.

Laminar flow of sulfuric acid solutions facilitates the passivation of stainless steel and does not affect corrosion in a passive range. Turbulent flow can have an adverse effect in the interval of acid high concentrations. The time to spontaneous activation gets shortened by the flow of concentrated acid.

Stainless steels can be anodically protected even in environments where sulfuric acid is mixed with organic substances, for example, in the production process of acrylamide, isobutylene, sulfonic acid, nitrobenzene, and others. AP is also possible in the presence of small amounts of chloride and fluoride ions. Their addition, however, gives rise to  $i_{cc}$  and  $i_p$  values and narrows the passive range.

#### 4.24.7.1.3 Titanium

The corrosion resistance of unprotected titanium in sulfuric acid is limited to concentrations below 10%. At 70 °C, however, the corrosion rate exceeds the threshold of 0.1 mm year<sup>−1</sup> even at low concentrations. Titanium is resistant at the boil only in solutions with concentration below 0.1% (**Figure 16**). Concentration dependence of unprotected titanium corrosion rate shows two maxima, the first at 40% and the other at 80%.

The anodic polarization of titanium in sulfuric acid solutions leads to passivation after the passage through the active range. Further polarization to high positive potentials (over 2 V(SHE)) makes the current grow gradually, but the passive layer remains stable up to very high values, even over 80 V. The growth of current in this range is not interrelated with the growth of corrosion rate, it is rather given by the oxygen evolution rate that is limited by high over-voltage resulting from low electron conductivity of the passive layer.

Current–time potentiostatic dependencies show that current drops at high positive potentials with time to relatively low values; the proportion of corrosion reaction on such current amounts from tenths to percentage points at maximum. Currents

**Figure 16** Range of corrosion rates below  $0.1 \text{ mm year}^{-1}$  for titanium in sulfuric acid (closest hatching – without AP, thin hatching – with AP).

exceeding the potential of 2 V(SHE) are always higher than those within the interval from 0.5 to 2 V (SHE).

The use of protection potential over 0.6 V(SHE) provides sufficient protection under all conditions where AP of titanium in sulfuric acid is effective. Optimal values of protection potential, in terms of both corrosion and consumption of protection current, range from 0.6 to 1.5 V(SHE). If it is necessary to increase the throwing power of the protection, high potential values, such as 12–15 V, can be used for polarization. Corrosion is not tremendously accelerated, and thereby, only the consumption of protection current is higher.

The critical passivation current density also depends on the acid concentration and grows within the exploitable concentration interval (Figure 17). Temperature dependence of  $i_{cc}$  and  $i_p$  currents is expressed by the activation energy from 60 to 75  $\text{kJ mol}^{-1}$ .

The corrosion graph in coordinates of sulfuric acid concentration–temperature is depicted in Figure 16. It is apparent from the graph that AP substantially widens the range of titanium corrosion resistance in sulfuric acid. Another important feature is the resistance of anodically protected titanium within the range of concentrations from 30 to 60% at elevated temperatures, when even the use of AP cannot guarantee sufficient resistance of stainless steels.

Another significant advantage of AP of titanium in sulfuric acid is its efficiency even at the presence of

**Figure 17** Dependence of passivation current density ( $i_{cc}$ ) of titanium on the sulfuric acid concentration (wt%).

substances aggravating the passivity of stainless steels (chloride ions, sulfides). Chlorine bubbling has an oxidizing effect on titanium in sulfuric acid, which can be used for protection above the electrolyte level. The stability of a passive layer on titanium is considerably high, and when the polarization current source is switched off, it gets activated no sooner than after several hours. AP of titanium is not applicable if even small amount of fluorides is present in the solution.

Laboratory experiments as well as operation installations proved the efficiency of AP of titanium on sulfuric acid solutions in the presence of sodium sulfate, zinc sulfate, sulfane (hydrogen sulfide), and carbon sulfide. AP can be also used for titanium alloys, but we definitely cannot expect better results than those with pure titanium. Alloys with molybdenum have the passive range limited by the transpassivation potential of 0.75 V(SHE) and alloys with chromium by the transpassivation potential of 1.2 V(SHE).

Low passivation currents facilitate the passivation of titanium compared with stainless steels. Because of the passive range unlimited by transpassivity, it is possible to provide protection by polarization under constant terminal voltage.

#### 4.24.7.2 Other Inorganic Acids

The aggressiveness of phosphoric acid depends on its purity, which is indicated by the production method. Technical phosphoric acid contains sulfates, fluorides, chlorides, and other anions. Carbon steel is

attacked by both pure and technical phosphoric acid within the entire concentration interval. The resistance of stainless chromium–nickel steels in phosphoric acid is good. Up to 50% concentration, all of their types resist even at a temperature of 100 °C; at higher concentrations, it is especially the composition of austenitic stainless steel that applies. Steels alloyed with molybdenum show sufficient resistance at all concentrations up to 90 °C.

Technical phosphoric acid is more aggressive to stainless steels, particularly in terms of the content of chlorides and fluorides (fluorosilicates). The corrosion rate then exceeds the acceptable thresholds even at low concentrations of these anions. Pitting corrosion occurs in 75% phosphoric acid containing chlorides in the amount within 15–20 mg l<sup>-1</sup>. Titanium shows much worse resistance against phosphoric acid than do stainless steels.

Carbon steel can be passivated in concentrated solutions of phosphoric acid and the passive range in 75% acid at normal temperature lies within 0.6 and 1.75 V, but currents in the passive range are high and the corrosion rate substantially exceeds 0.1 mm year<sup>-1</sup>. Slightly better results can be achieved with AP of carbon steel in mixtures of phosphoric and sulfuric acids. In general, we cannot expect that AP of carbon steel in phosphoric acid will be used more widely.

The passivity of stainless steels in pure concentrated phosphoric acid ranges in the interval of potentials from 0.3 to 1.2 V(SHE). Currents in the passive range are, by orders of magnitude, lower than those of carbon steel, and the AP can thus be considered even for higher temperatures.

It is shown in the corrosion graph (Figure 18) that was set up for pure phosphoric acid. What is probably more important than AP of stainless steels at high temperatures in pure acid is the possibility to reduce high corrosion aggressiveness of phosphoric acid contaminated with chlorides and fluorides.

Although the application of AP to titanium in phosphoric acid substantially widens the range of temperatures and concentrations at which the titanium corrosion resistance is below 0.1 mm year<sup>-1</sup>, there is a number of cheaper metallic materials that, even unprotected, are much more resistant (e.g., stainless steels and lead). AP of titanium could be considered effective in phosphoric acid solutions containing higher amount of chlorides, with no fluorides though.

With hydrochloric acid, it is only possible to consider the AP of titanium. The corrosion resistance of

**Figure 18** Range of corrosion rates below 0.1 mm year<sup>-1</sup> for stainless steel FeCr18Ni10(Mo) in phosphoric acid (closest hatching – without AP, thin hatching – with AP).

unprotected titanium in hydrochloric acid is limited to low concentrations only, according to the presence of oxygen and other oxidizing elements.

The titanium passivation potential shifts with the growth of hydrochloric acid concentration to positive values and the protection potential above 0.4 V(SHE) guarantees effective protection at all concentrations and temperatures suitable for the AP of titanium (Figure 19). The optimal interval of protection potentials ranges from 0.5 to 1.5 V(SHE). At potentials over 5 V(SHE), the passive layer is broken through and titanium is attacked by pitting corrosion.

The corrosion graph with coordinates of hydrochloric acid concentration–temperature (Figure 20) clearly shows that AP widens the corrosion resistance of titanium from 20 to 50 °C to the entire concentration interval.

AP of stainless steel can be effective also in nitric acid containing chlorides, where nitrate anions substantially inhibit formation of pitting corrosion.

#### 4.24.7.3 Organic Acids

The anodic passivation of metals is also possible in aqueous solutions of organic acids, though the specific conductivity of their pure solutions is usually less than 1 S m<sup>-1</sup> at normal temperature (save for the oxalic acid, the conductivity of which exceeds 1 S m<sup>-1</sup> already from 1%).

There are just seldom literature references regarding the AP of titanium, carbon steel, stainless steels,

**Figure 19** Dependence of titanium passive range on the hydrochloric acid concentration ( $W$ ) (close hatching – potential range suitable for AP).

nickel, and its alloys in formic, acetic, oxalic, lactic, citric, and sulfane acids.

#### 4.24.7.4 Inorganic Salts

##### 4.24.7.4.1 Ammonium nitrate

Ammonium nitrate is widely used as a part of liquid nitrogen fertilizers, and very often, is the most aggressive part of such solutions. With increasing concentrations of ammonium nitrate from 10 to 60%, the carbon steel corrosion rate grows up to the maximum at 40% concentration. Stainless steels are resistant in the ammonium nitrate environment.

Besides free ammonia, nitrogen fertilizers also contain urea, which acts there as a solvent. The addition of urea slightly reduces the corrosion aggressiveness of ammonium nitrate, still the corrosion rate is technically unacceptable. A substantial reduction of corrosion aggressiveness of the  $\text{NH}_4\text{NO}_3\text{--CO}(\text{NH}_2)_2\text{--H}_2\text{O}$  system can be achieved by addition of ammonia up to 3%. The possibility to anodically protect carbon steel in ammonium nitrate solutions with  $\text{pH} = 4.5\text{--}11$  is addressed already by the first studies on AP. Another type of liquid fertilizers containing high amount of ammonium nitrate, where AP of carbon steels can be used, are solutions containing ammonium carbonate. Corrosion resistance of carbon steel in ammonium nitrate solution containing calcium carbonate can be increased by anodic passivation.

**Figure 20** Range of corrosion rates below  $0.1 \text{ mm year}^{-1}$  for titanium in hydrochloric acid (closest hatching – without AP, thin hatching – with AP).

The most widespread type of an ammonium nitrate-based liquid fertilizer is the solution containing 40–45% of ammonium nitrate, 25–30% of urea, and 20–30% of water, (UAN): carbon steel can be placed in the liquid fertilizer UAN in both active and passive state within the whole range of pH values (5–9). At  $\text{pH} < 7$ , the originally passive surface spontaneously activates and the passive state can be restored only by AP. However, the increase of pH values over 7.5 after the steel activation does not induce spontaneous passivation, but accelerates the corrosion rate. At  $\text{pH} > 7.5$ , the passivated surface (oxidized in air) does not activate and the AP is not essential.

##### 4.24.7.4.2 Sulfates, phosphates, chlorides, thiocyanates

Neutral sulfate solutions do not cause any major problems due to their corrosion aggressiveness to metallic materials. Corrosion is affected, in particular, by the solution pH and by the content of substances influencing the oxidation–reduction potential of a metal. Corrosion aggressiveness grows with the drop of the pH value of the solutions.

The applicability of AP to stainless steels was verified for solutions of zinc sulfate, manganese sulfate, aluminum sulfate, alums, hydroxylammonium-sulfate, and ammonium sulfate.

Ammonium sulfate is present in extremely acidic solutions where AP of stainless steel can be applied, similar to the production of formic acid.

High aggressiveness of sulfate against carbon steel can be mitigated by AP. It is advantageous in solutions containing ammonium nitrate, which suppresses the activating effect of sulfates on steel. Solutions of hydroxylammonium sulfate ( $\text{NH}_3\text{OH}\text{SO}_4$ ) used in the  $\epsilon$ -caprolactam production process are very aggressive because of their hydrolyzing effect and the content of free 10% sulfuric acid. Unprotected stainless steels in active state corrode in this solution at elevated temperatures. The behavior of the solution is analogous to that of the sulfuric acid solution and the salt itself does not participate significantly in its corrosion aggressiveness. Similarly, to sulfuric acid, AP of stainless steel ensures high corrosion resistance in this environment.

Mixtures of phosphates and sulfates make the fundament of combined fertilizers. Parameters of stainless steel AP were verified just for the conditions in reactors for the production of such fertilizers. The conditions of producing fertilizers by the decomposition of apatite by sulfuric and nitric acid, after ammoniation and addition of potassium chloride solution, give rise to the formation of a solution inducing pitting corrosion of stainless steel. This can be eliminated by AP over the inhibition potential, which exists at polarization curves, depending on the steel composition, temperature, and the content of chlorides and nitrates in the solution.

Stainless steel in active state can corrode in thiocyanate solutions ( $\text{SCN}^-$ ). Its passivation can be achieved by anodic polarization, but the passive range is limited by potential, above which thiocyanate oxidizes. With AP, it is possible to mitigate the corrosion of FeCr18Ni10MoTi steel at temperatures between 90 and 120 °C in concentrated sodium thiocyanate solutions, and thus, reduce the iron content in the solution. Iron ions enter the solution due to the equipment corrosion and thus slow down the polymerization in the production process of polyacrylonitrile fiber.

#### 4.24.7.5 Aqueous Solution of Ammonia

Aqueous solutions of ammonia are not very aggressive toward carbon steel (the corrosion rate is below  $0.1 \text{ mm year}^{-1}$ ), though the corrosion rate may reach the values of  $0.5 \text{ mm year}^{-1}$ , if the solution contains a small amount of other substances. The corrosion rate of carbon steel depends not only on the content of these substances ( $\text{CO}_2$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{CH}_3\text{COO}^-$ ), but also on the content of oxygen, the pH of the solution, and ammonia concentration (pH of the solution does

not depend only on the ammonia concentration but also on the content of other substances). Up to 5% of ammonia, carbon steel passivates spontaneously. At higher concentrations and  $\text{pH} < 12$ , passive steel spontaneously activates. At  $\text{pH} > 12$ , the activation depends on the oxygen content in the solution, the superficial state, and other factors. The corrosion rate of active specimens grows with the access of oxygen, whereas, in case of passive specimens, the effect of oxygen is positive.

The specific conductivity of pure ammonia solutions is very low, but in operation conditions, achieves values up to  $10 \text{ S m}^{-1}$  due to contamination.

The curves of potential–current polarization dependencies for carbon steel in pure aqueous ammonia solutions with concentration exceeding 25% have a shape analogous to Type-III in Figure 2(b). The corrosion rate within the passive range is negligible, thousandths to hundredths of  $\text{mm year}^{-1}$  in the order of magnitude. The content of oxygen positively affects the effectiveness of AP, and thus, it is advisable to ensure oxygen access to the metallic surface by stirring the solution.

#### 4.24.7.6 Hydroxides of Alkaline Metals

Nonalloyed steels have, in sodium hydroxide solutions up to 60 °C, a very low corrosion rate of  $0.1 \text{ mm year}^{-1}$  for all concentrations (Figure 21). In 15% solution of sodium hydroxide, they show sufficient resistance even at the boil. However, the occurrence of corrosion cracking is more important than the uniform corrosion rate. The range of possible occurrence of corrosion cracking is defined in the sodium hydroxide concentration–temperature graph (Figure 21) by curve 2. Its position shows that it is this dependence that is decisive for the use of nonalloyed steels in the sodium hydroxide solutions rather than the isoline of corrosion rate  $0.1 \text{ mm year}^{-1}$ .

The specific conductivity of solutions of alkaline metal hydroxides exceeds  $10 \text{ S m}^{-1}$  at normal temperature within the almost entire concentration interval.

AP in sodium hydroxide solutions is important particularly for nonalloyed and low-alloyed steels. At higher temperatures and pressures, or at higher concentrations of sodium hydroxide, AP of austenitic stainless steels can be considered.

The anodic polarization of nonalloyed and low-alloyed steels in the sodium hydroxide solution leads to passivation, and the shape of the curves strongly depends on the presence of oxidizing agents and other substances. The range of potentiodynamic

**Figure 21** Range of corrosion rates below  $0.1 \text{ mm year}^{-1}$  for mild steel in sodium hydroxide. 1 – corrosion rate  $0.1 \text{ mm year}^{-1}$  without AP, 2 – limit of possible SCC occurrence without AP (closest hatching – without AP, thin hatching – with AP).

dependencies in 35% solution of sodium hydroxide at the boil is depicted in **Figure 22**.

The passive range relating to sodium hydroxide concentrations from 5 to 50% lies within the potential interval from  $-0.7$  to  $0.5 \text{ V(SHE)}$ . However, only the part where corrosion cracking does not occur is exploitable. Having summarized the data of various authors, we can claim that the safe range for AP lies above the potential of  $-0.3 \text{ V(SHE)}$ .

The corrosion graph with coordinates of sodium hydroxide concentration–temperature (**Figure 21**) delimitates the likely range of AP for the elimination of corrosion cracking and the mitigation of uniform corrosion.

The greatest aggressiveness is shown by 50% sodium hydroxide solution; however, in this solution, AP is successful up to the temperature of  $80^\circ\text{C}$ . At lower concentrations, AP can be effective even in pressure equipment where temperature exceeds the boiling point under atmospheric conditions.

AP of carbon steel in the sodium hydroxide solution is feasible in both the solutions used in the technology of aluminum oxide production and in the presence of chlorides and sulfides, that is, in solutions used in the paper and cellulose production process.

The aggressiveness of potassium hydroxide is higher compared with sodium hydroxide, and the scope

**Figure 22** Courses range of potentiodynamic curves of carbon steel in 35% sodium hydroxide at boiling point (SCC – potential range of SCC).

of usability of unprotected carbon steel is narrowed for the same concentrations by 20–30K from the perspective of both the uniform corrosion and corrosion cracking. The polarization properties of carbon steels in potassium hydroxide solutions do not differ much from those of solutions of sodium hydroxide. Even the potential ranges of corrosion cracking are similar.

#### 4.24.7.7 Melts

If the corrosion in a melt is controlled by electrochemical process and the melt has a sufficient ion conductivity, AP can mitigate corrosion attack in this environment as well. The specific conductivity of melts of inorganic salts and hydroxides usually exceeds  $100 \text{ S m}^{-1}$ . Stainless steel can be anodically passivated in  $\text{NaOH-Na}_2\text{SO}_4$ ,  $\text{NaOH-Na}_3\text{PO}_4$ ,  $\text{NaOH-KCl}$ ,  $\text{NaOH-NaCl-Na}_2\text{CO}_3\text{-NaNO}_3$ , and  $\text{NaOH}$  melts at temperatures up to  $1000^\circ\text{C}$ .

Glass is electrically melted by alternating current and molybdenum electrodes. Problems with the corrosion of heating electrodes arise when the glass melt contains ions of metals, such as lead, arsenic, or antimony, which reduce at the electrode surface along with the oxidation of molybdenum. The reduced metal can form compounds with molybdenum, which further accelerates the corrosion of the electrodes. Laboratory experiments proved that a protective layer forms on the molybdenum surface during the anodic polarization in the glass melt, which protects the electrode

surface against corrosion, and at the same time, does not overly constrain the passage of alternating current that electrically heats the glass melt. The specific conductivity of the glass melt strongly depends on the type of glass; values at the refining temperature typically range from 20 to 50 S m<sup>-1</sup>.

#### 4.24.7.8 Electroless Nickel Plating Baths

The reason for AP in electroless (chemical) metal plating baths is the necessity to avoid undesirable deposition of metals on the walls of the metal plating equipment rather than corrosion protection.

The electroless nickel plating baths are the most widespread. The deposited coating is an alloy of Ni–P, or Ni–B, according to the type of the used reduction agent. Especially, sodium hypophosphite (NaH<sub>2</sub>PO<sub>2</sub>) or sodium tetrahydridoborate (Na[BH<sub>4</sub>]) is used as a reduction component of the baths.

Electroless nickel plating is an electrochemical process, in which reduction reactions lead to the formation of nickel and hydrogen, and oxidation reactions turn hypophosphite to phosphate, or phosphate. These reactions optimally proceed at temperatures from 90 to 95 °C.

Reactions can proceed at any surface showing a catalytic effect and enabling a charge transfer. The idea of using anodic polarization to protect the walls of the production equipment from the deposition of nickel was brought in the mid-1960s by German authors.

Anodic polarization can be used only for materials that do not suffer from corrosion (get passivated) and upon which the oxidation of solution elements is restricted. Electroless metal plating baths contain substances of a reduction nature, and therefore, the oxidation reaction upon the surface of the used material must have a high overvoltage.

Considering the nickel plating baths, these requirements are complied with by stainless steels and titanium within the entire range of pH values. In addition to that, nickel can be used in alkaline baths.

The spontaneous nickel deposition process starts at temperatures exceeding 60 °C, which is the temperature limit of the effective use of AP. The specific conductivity of nickel plating baths ranges from 3 to 30 S m<sup>-1</sup> at operation temperature according to the composition. The interval of protection potentials for stainless steel in the environment of electroless nickel plating baths depends on the type of the bath, but for most acidic baths, it ranges from –0.25 to 0.8 V(SHE), the optimal potential interval is 0.5–0.8 V(SHE).

The passive range of stainless steels is wider than that indicated by the interval of protection potentials, and the corrosion rate within this range is negligible. The upper potential limit of the protection interval is given by the substantial growth of current resulting from the oxidization of the solution components, probably of the hypophosphite to phosphate, while the lower limit lies right above the starting point of spontaneous deposition of metallic nickel (–0.35 V (SHE)). The actual exploitable range of potentials is narrower, since the spontaneous potential of passivated stainless steel corresponds to ~0.25 V(SHE). Without polarization, this potential remains stable at maximum for several hours in the operation conditions. Then, nickel deposits on the walls, and the potential shifts in the negative direction to the value held by the metallic surface self-plated with nickel (–0.35 to –0.44 V(SHE)).

Current densities passing through the anodically protected surface of stainless steel at protection potential represent the rates of suppressed oxidation of the solution components rather than the corrosion rate.

The range of titanium protection potentials is wider and the protection current is lower than that of stainless steel. The overvoltage of anodic oxidation of hypophosphite is higher on passive titanium. Even the resistance of passive titanium against nickel deposition without AP is higher. It is possible to anodically protect stainless steels in baths containing chlorides and fluorides, but the interval of protection potentials is narrower. The use of titanium in baths containing fluorides is precluded.

#### 4.24.8 Industrial Applications of AP

Detailed information on industrial applications can be found in monographs<sup>6–9</sup> on AP and in surveys in journals<sup>5,10–13</sup> and other sources<sup>27,34</sup>

##### 4.24.8.1 Sulfuric Acid Coolers Made of Stainless Steel

A great deal of heat is released in the production of sulfuric acid and this heat must be transferred by the cooling of the acid circulating in the production equipment. Mostly, it is acid with 93% or 99% concentration, and in some cases, even lower (up to 75%). The acid is predominantly cooled from 90 to 40 °C and the maximum temperature is limited by the corrosion resistance of the cooling set. The first and the most widespread coolers of this type to date

are vertical and horizontal shell and tube anodically protected heat exchangers with water in pipes and acid flowing in the anodically protected intertubular space<sup>13,27,28,33</sup> (**Figure 23**).

The construction of heat exchangers with water as cooling medium with acid in pipes is less frequent. Sporadic are data on anodically protected desk coolers; more data can be found regarding spiral coolers.<sup>29,30</sup> AP is also used for air coolers.<sup>11,14,28</sup> Even the tubes for acid transportation are anodically protected.<sup>31,32</sup> Cathodes are mostly made of either stainless steel or nickel alloys<sup>48</sup>; reference electrodes are either made of mercury sulfate or platinum.

A competitive solution to the AP of common austenitic stainless steel coolers is the use of high-silicon stainless steels that resist without AP.

The installations of anodically protected coolers of 75–78% sulfuric acid<sup>13</sup> in plants processing calcining gases from ferrosins production (**Figure 24**) are rather unusual due to the threshold concentration and temperature.

#### 4.24.8.2 Stainless Steel Equipment Operating in Environment Containing Sulfuric Acid

The AP was described for transportation stainless steel vessels, measuring vessels, neutralization vessels for sulfonic acid, hydrolysis vessels, hydroxylammoniumsulfate storage vessels, heating coil, and turbo-coolers of 55–65% sulfuric acid. Stainless steel was also used for the anodically protected vessel for storing pure sulfuric acid (94–99%) at temperatures up to 40 °C (**Figure 25**).

#### 4.24.8.3 Other Anodically Protected Equipment Made of Stainless Steels

The industrial application of AP was described for storage vessels of technical concentrated phosphoric acid, reactors for the production of combined fertilizers containing chlorides,<sup>34</sup> and sodium thiocyanate evaporator.<sup>34</sup>

#### 4.24.8.4 AP of Stainless Steel in Chemical (Electroless) Nickel Plating Bath

The vessels for chemical nickel deposition are numerous groups of anodically protected industrial installations. Instead of corrosion resistance, the AP prevents, in this case, the undesirable deposition of nickel on the stainless steel tank walls. Anodically

**Figure 23** Anodically protected stainless steel heat exchangers for cooling of 93–98 wt% sulfuric acid.

**Figure 24** Anodically protected stainless steel heat exchangers for cooling of 75–78 wt% sulfuric acid.

protected titanium tanks are also used for current-free nickel plating. AP has become a standard equipment of operation lines for chemical nickel plating.<sup>13,35</sup> Due to the passage of current, nickel deposits on a cathode usually made of stainless steel. Stainless steels, where nickel spontaneously deposits, serve as a reference electrode. Nickel can be regularly removed from electrodes mechanically as well as by dissolution in nitric acid.

#### 4.24.8.5 Carbon Steel Storage Vessels for Concentrated Sulfuric Acid

In addition to corrosion protection, the AP of sulfuric acid storage tanks made of carbon steel ensures high purity of the stored acid. The AP keeps the iron content in the stored acid on the ppm level, while in the case without AP, there are tens of ppm. Cathodes are made of stainless steel, reference electrodes are either mercury sulfate or platinum. There are a

**Figure 25** Anodically protected tank for storing pure sulfuric acid (94–99%) at temperatures up to 40 °C.

number of literature data on AP of these vessels.<sup>13,36</sup> For waste acid, it deals only with the reduction of the corrosion rate.

#### 4.24.8.6 Carbon Steel Equipment for Alkaline Environments

In case of anodically protected carbon steel storage tanks of sodium hydroxide, change of potential in the passive area leads to values, at which intergranular SCC is eliminated.<sup>11,13,37</sup> Susceptibility to corrosion cracking can be eliminated in potassium hydroxide.<sup>5,28</sup> Cathodes can be made of nickel, reference electrodes of mercury oxide.

Tubular evaporators are complicated pressure vessels operating with AP in the sodium hydroxide environment.<sup>5,28</sup> The AP was also used for the protection of steel equipment in the production of aluminum oxide.

#### 4.24.8.7 Cellulose Boilers and Other Equipment in Paper and Cellulose Industry

Batch and continuous digesters made of carbon steel<sup>38–41</sup> and a Kraft liquor tankage<sup>42–44</sup> are the main anodically protected objects. Reference electrodes are silver sulfide or molybdenum. The electrochemistry of Kraft liquors is complicated because of multiple oxidation states of sulfur compounds (thio-sulfate, polysulfide). Potential–current dependencies have the shape of I–III (**Figure 2**) in this corrosion system. For batch digesters, it is necessary to rate the direct current sources for periodic passivation.

AP is the most effective protective measure against SCC and it is possible to overcome erosion–corrosion problems. The industrial success of AP resulted in many commercial installations in North America and Finland (Savcor<sup>27</sup>).

#### 4.24.8.8 Liquid Fertilizer Storage Tanks

The AP of carbon steel in liquid fertilizer containing ammonium nitrate is described in literature<sup>13</sup>; however, it is not used much in operation any longer. If we compare the AP with other alternatives of the corrosion protection of steel-welded equipment, we will find out that operation-wise, the protection is simpler if ammonia leakage is avoided so that the pH of the solution does not drop below 7.5 and the steel surface is spontaneously passive.

AP is used for ammonium carbonate fertilizers containing ammonium nitrate and for ammonia–water storage tanks, and in the production of ammonium carbonates.<sup>45</sup>

#### 4.24.8.9 Equipment Made of Other Metallic Materials

The AP of a titanium exchanger was described for the viscose production process, in which diluted solutions of sulfuric acid containing other substances are used.

Documented information about the industrial application is available also for molybdenum heating electrodes in glass melt.<sup>46,47</sup>

**CAR** Corrosive agent removal  
**CI** Corrosion inhibitor  
**CR** Corrosion rate  
**IE** Inhibitor efficiency  
**PBI** Protective barrier inducement  
**RH** Relative humidity

### Symbols

**C** Concentration of species in solution  
**C<sub>crit</sub>** Critical concentration for effective inhibition by anodic passivating inhibitors  
**i<sub>corr</sub>** Corrosion current density  
**i<sub>L</sub>** Limiting current density for an electrochemical reaction, usually in the context of oxygen diffusion to a cathode  
**i<sub>crit</sub>** Critical current density required for passivation  
**θ** Fractional surface coverage, where  $\theta = 1$  is one monolayer

### 4.25.1 Introduction

Materials selection, substrate (surface) design engineering (e.g., by use of coatings), and environmental modification (e.g., application of a corrosion inhibitor (CI)) are three commonly accepted strategies for corrosion control. The first two of these approaches can be described formally as *ex situ*, and ideally would be sufficient for complete protection. Practically, however, cost-effective corrosion control

typically requires the use of a relatively cheap material that serves the desired mechanical or physical function (e.g., commonly a carbon or low-alloy steel). In such cases, *in situ* environmental modification is often required to control the corrosivity of the ambient fluid (i.e., gas or liquid environment or atmosphere) in which a material is immersed. There are a variety of technologies available to achieve this end, and selection ultimately depends upon the specific details of the particular application, generally driven by the requirement to achieve acceptable performance for minimum cost. The scientific basis behind environmental modification can be divided into two fundamentally different underlying strategies:

- Corrosive agent removal (CAR): This involves deliberate modification of an environment in order to reduce its chemical and/or electrochemical activity towards a substrate material by removal of specific corrosive reagents.
- Protective barrier inducement (PBI): This involves the deliberate addition of a chemical species that interacts in some way with the corroding substrate so as to form a protective barrier that reduces the corrosion rate (CR) to an acceptable level.

It is important to note that these strategies may be combined together (and indeed also combined with one of the *ex situ* corrosion control methods – for example, the addition of corrosion inhibitors (CIs) to organic coatings) in order to achieve the desired performance. In this chapter, an introduction to the fundamentals of environmental modification for corrosion control is presented. Industrial practice is discussed in the following chapters of this section.

### 4.25.2 Corrosive Agent Removal (CAR)

The process of corrosion involves two simultaneous electrochemical reactions (i.e., the anodic and the cathodic), which occur necessarily at the same rate but at different physical locations, and which involve the transport of ionic current in an electrolyte, see **Figure 1**. Thus, the scientific basis for reducing the kinetics of the corrosion process involves interference with one or more of these electrochemical processes. From inspection of **Figure 1**, it can be deduced that there are three basic CAR strategies for reducing the rate of the electrochemical reactions associated with corrosion, they are:

- removal of the cathodic reactant (e.g., oxygen) such that the cathodic reaction is stifled;
- removal of the electrolyte solution (e.g., water) such that, in particular, the anodic reaction becomes stifled since metal ions have limited ability to be solvated; and
- reduction of the electrolyte conductivity such that a large resistance is developed between the anode and the cathode and, hence, the electrochemical corrosion current is stifled.

Determination of which fluid components to target is dependent upon both the environment and practical application. For example, it is not practical to deionize an oilfield seawater injection well system.

#### 4.25.2.1 Gaseous Environments

Focusing on gaseous environments, a pertinent topic is corrosion of substrates exposed to the atmosphere. Common scenarios include: outdoors in the open air, indoor environments, packaging for long-term storage of materials, and mothballing of equipment for

**Figure 1** Schematic diagram of a corrosion process showing spatial separation of anode from cathode with corresponding migration of ions in solution and with oxygen as the cathodic reactant.

maintenance. While the first of these cannot be addressed by environmental modification, the other scenarios are amenable to CAR.

Gaseous atmospheric corrosion involves the condensation of moisture from the atmosphere onto a substrate. Typically, for a clean, uncontaminated, and polished surface in an atmosphere containing no gaseous or solid particle (aerosol) pollutant species, corrosion is minimal below a relative humidity (RH) of  $\sim 80\%$ , where adsorbed water reaches a critical thickness of  $\sim 3\text{--}4$  monolayers.<sup>1</sup> If the surface is roughened or has a porous structure (as in a corrosion product) then capillary condensation takes place at lower RH; where chemical salt contamination exists, is deposited, or forms on a surface by reaction, then water condensation will occur at the humidity of deliquescence of the salt. In all of these scenarios, corrosion is only of significance where the RH is greater than a critical value that depends on the surface condition (or contamination) of the substrate.<sup>2,3</sup> Corrosion can thus be suppressed by deliberate removal of water vapor from the atmosphere so as to reduce the RH to below the critical value for the onset of corrosion. RH can be calculated from the following expression:

$$\text{RH} = \frac{p_{\text{H}_2\text{O}}}{p_{\text{H}_2\text{O}}^*} \times 100\% \quad [1]$$

where  $p_{\text{H}_2\text{O}}$  is the water vapor partial pressure and  $p_{\text{H}_2\text{O}}^*$  the saturation water vapor partial pressure at the prevailing temperature. For a given absolute humidity (i.e.,  $p_{\text{H}_2\text{O}}$ ) the RH falls with increasing temperature but rises with decreasing temperature. This explains the well known phenomenon of condensation on cold surfaces.

For 'technically' clean substrates, the critical RH for the onset of significant corrosion is generally between 50% and 60%. However, for surfaces contaminated with sea salt, the critical RH corresponds to the RH for deliquescence of magnesium chloride ( $\sim 35\%$ ), while for historic artifacts derived from marine sources and, consequently, contaminated with chloride ion, the critical RH can be as low as 15% (the deliquescence RH for iron chlorides).<sup>4</sup>

For long-term storage of components, archaeological artifacts and for mothballing of equipment, environments of low RH are essential. For small components, this may be achieved by suitable packaging in materials with a low water vapor transmission rate, combined with a solid suitable desiccant. The familiar silica gel is commonly used; it functions best at around room temperature, and is capable of

bringing RH down from 60–90% to ~40%. Activated alumina, quick lime (calcium oxide), montmorillonite clay, aluminosilicates (zeolites) are other solid desiccants that are used for such applications. For larger components, as well storage warehouses, it may be cost effective to consider mechanical dehumidification (i.e., air conditioning). Further information on desiccants can be found in BS 1133 Part 19.<sup>5</sup>

Occasional, but important, applications also exist for removal of corrosive gas fractions (including water vapor) from industrial processes by direct absorption. For example, triethylene glycol is often employed in natural gas production facilities to remove water content before the gas is transported away. Other gaseous species are also sometimes targeted in gas phase CAR, including carbon dioxide, sulfur dioxide, and hydrogen sulfide. The release of corrosive vapors from packaging materials is also an important consideration. For example, the degradation of cellulose (paper, wood, etc.) and polymeric packing materials may release aggressive agents such as acetic acid and hydrochloric acid vapor.<sup>6</sup> Detailed information on indoors corrosion and on corrosion due to packaging materials can be found in Donovan's book.<sup>7</sup>

#### 4.25.2.2 Liquid Environments

Turning to CAR in liquid environments, water can be a major concern in nonaqueous systems. Thus, for scenarios where water is a nonessential constituent of the liquid, its removal is usually a desirable goal. For example, in oil production, water is commonly removed from the process fluid using separator vessels, which rely upon the different densities of oil and water; however, if the water exists as a stable emulsion then additional pretreatment is required. For some systems, it is preferable to retain a small amount of residual water in the nonaqueous medium, otherwise a protective passive film either may not be able to form, or may be unstable. Such environments include anhydrous liquid ammonia, where ~10 ppm water should be present to avoid stress corrosion cracking of steel<sup>8</sup> and chlorinated solvents, where a few ppm of water permits passivation and prevents the so-called 'bleeding corrosion' of aluminum.<sup>9</sup>

However, in aqueous environments, where water is the main component of the fluid or in those mainly nonaqueous environments where it is simply ubiquitous, then such a strategy is not feasible. Thus, CAR must target another relevant component of the environment. Noting, for example, that CRs in

deionized water are generally lower than in potable water or seawater, a common strategy for aqueous corrosion control is to lower the electrolyte conductivity. The mechanism for this effect is as indicated in **Figure 1**; thus, a higher electrolyte resistance reduces the current flowing from anode to cathode. This may be simply achieved by specific removal of those (electrolyte) species that are able to form ions in solution by pretreatment of the water that will be used in the system. However, it is important to remember that water softening, often carried out to prevent scaling in systems, replaces calcium ions with sodium ions, and will often increase electrolyte conductivity. Deionization (or rarely nowadays, multiple distillation) is, therefore, the only reliable mechanism for achieving the desired reduction in anion and cation electrolyte concentration.

The most commonly used (and often most effective) method of CAR, especially in near-neutral aqueous solutions, is the control of dissolved oxygen levels as, under these conditions, it is the reactant for the rate-limiting cathodic reaction, that is:

At room temperature, the concentration of dissolved oxygen in water in equilibrium with air is ~8 ppm (0.2 mM). This value is sufficient to cause appreciable corrosion of unprotected carbon steel (i.e., in the range ~0.2 to  $\gg 1 \text{ mm year}^{-1}$  depending on fluid flow rate). A typical aim is to lower the CR to an acceptable level, that is, below ~0.1 mm year<sup>-1</sup>. A good 'rule of thumb' that will generally achieve an acceptable CR for carbon steel equipment in flowing seawater is to reduce the dissolved oxygen content to 20 ppb (~0.0006 mM) or below,<sup>10</sup> which is readily achievable by mechanical deaeration.

The concentration of dissolved oxygen in water can be reduced by physical methods, chemical methods, or a combination thereof. Physical methods (often called mechanical deaeration) include heating the water, as O<sub>2</sub> solubility decreases with increasing temperature. In boiler systems, water heating is often combined with vacuum deaeration and/or gas sparge stripping. The former process involves lowering the gas pressure above the water hence leading to a reduction in dissolved gas content, while in the latter technique, a counter-current of gas (e.g., nitrogen, steam) mixes intimately with the water replacing dissolved O<sub>2</sub>.

Chemical methods for removal of dissolved O<sub>2</sub> are commonly known as oxygen scavengers and function by reacting directly with residual O<sub>2</sub> to form another,

more innocuous, species. Commonly they are only economic in closed systems such as boilers. Traditional oxygen scavengers suitable for low-to-medium pressure boilers include sulphite anions ( $\text{SO}_3^{2-}$ ) and tannins.<sup>11</sup> The former reacts as follows:

The sulfite is added either as sodium sulfite ( $\text{Na}_2\text{SO}_3$ ), or ammonium bisulfite ( $\text{NH}_4\text{HSO}_3$ ). Note that commensurate with a reduction in oxygen level, the use of sulfite will result in an increase in the quantity of dissolved solids in the system (as sulfate) and consequent increase in electrolyte conductivity. For high pressure and high performance boiler systems (such as in power generation), alternative oxygen scavengers are required that leave no residue. Traditionally, hydrazine has been used for this purpose, reacting as follows:

However, the use of hydrazine is increasingly deprecated due to its toxicity. Alternatives include carbohydrazide, which reacts with oxygen to form  $\text{CO}_2$ ,  $\text{N}_2$ , and  $\text{H}_2\text{O}$ .

Another solution species, which is important in determining corrosivity, is the hydrogen ion ( $\text{H}^+$ ). As the concentration of this species increases, pH decreases, and the CR usually rises. The reason for the occurrence of this phenomenon for iron can be understood from Figure 2, which depicts a Pourbaix

(E–pH) diagram for this substrate. Domains of thermodynamic phase stability for soluble species (i.e., regions of corrosion), insoluble species (e.g., oxides), and the metallic phase (i.e., where oxidation of the metal is thermodynamically impossible) are displayed. Corrosion can be greatly suppressed if the pH is controlled (raised for iron according to Figure 2) to maintain the material within a domain in which a solid phase has significant thermodynamic (or kinetic) stability, that is, in a region of passivity. Thus, water treatment often includes a deliberate reduction in the level of hydrogen ions by the addition of a base such as ammonia, carbonate, or hydroxide, to maintain passivity of the metal.

For more details on water treatment, especially for boiler feedwaters, the reader is referred to the relevant chapter of this section.

#### 4.25.3 Protective Barrier Inducement (PBI)

PBI involves *in situ* substrate/fluid interface modification to impede one or more steps in the corrosion process, for example, metal dissolution. Typically, such surface engineering is achieved through addition of one, or more, chemical reagents to the system, which affect synthesis of a protective substrate adhered layer.

**Figure 2** Pourbaix diagram for iron, drawn for a metal ion concentration of  $10^{-5}$  M.

One can also consider cathodic protection to be a form of PBI (e.g., in the formation of calcareous films in sea water) but this topic will not be discussed further here as it is well covered in other sections.

One route to *in situ* protective layer formation is through initiating precipitation of low solubility inorganic compounds out of solution, such as calcium carbonate ( $\text{CaCO}_3$ ). If the resulting solid forms a substrate bound scale, displaying low porosity/permeability, it can provide significant protection against corrosion. To stimulate the deposition of such a layer, there must be a change in the environment, so that the concentration of the scaling compound in solution exceeds its solubility. This shift may be affected by introducing more of a component of the scaling compound to the aqueous phase, for example, to promote growth of  $\text{CaCO}_3$  scale, one could add either  $\text{Na}_2\text{CO}_3$  or  $\text{Ca}(\text{OH})_2$ . Another option is pH modification. Typically, the pH is raised through, for example, addition of  $\text{NaOH}$  to encourage scaling. These approaches have been applied in practice to control corrosion in potable water supplies where there are lead/copper pipes and few, if any, acceptable alternatives.<sup>12</sup> In other engineering applications, scale formation is undesirable, since it can interfere with the intended process, for example, greatly reduces the efficiency of heat exchange surfaces. A more detailed discussion of these matters can be found elsewhere in this section.

Alternatively, PBI can be accomplished through addition of chemicals known as CIs to the fluid environment. In BS EN ISO 8044:2000<sup>13</sup> the definition of such a species is:

chemical substance that when present in the corrosion system at a suitable concentration decreases the corrosion rate, without significantly changing the concentration of any corrosive agent.

This rather succinct description may be augmented by adding that these substances decrease the CR by bringing about a change at or near the substrate surface, that is, they induce a protective surface barrier. The exact nature of this barrier varies with both the identity of the CI and the environment. For example, it may comprise either a 2-D monolayer or submonolayer comprising a single molecule or ion thickness, or a macroscopic 3-D film. Note that in the ISO definition, species such as oxygen scavengers are not considered to be CIs, as they do significantly change the concentration of a corrosive agent, i.e., they remove the  $\text{O}_2$ . Some authors, incorrectly, do not make this distinction.

Specific inhibitive species are further defined on the basis of one or more characteristics, including the dimensionality of the induced barrier. The terms ‘adsorption’ and ‘film-forming’ are used to classify inhibitors that induce 2-D and 3-D layers, respectively. Other characteristics by which CIs can be categorized include the following:

*Organic/Inorganic* – indicates the composition of a CI using the conventional chemical terminology for compounds.

*Anodic/Cathodic/Mixed* – specifies which electrochemical reaction is stifled by the CI; a mixed inhibitor interferes with both anodic and cathodic processes.

*Oxidizing/Nonoxidizing* – denotes whether or not dissolved oxygen is required for the inhibitor to function efficiently. As discussed later, this terminology is usually restricted to anodic inhibitors operating in near-neutral solutions.

*Safe/Dangerous* – refers to how corrosion proceeds at inhibitor concentrations that are insufficient for effective protection. For a *dangerous* inhibitor, the CR rises abruptly to approximately the same as, or greater than, that of the uninhibited system and localized corrosion (e.g., pitting) can occur. However, neither local corrosion nor a step-wise increase in rate, occurs for a *safe* inhibitor; rather there is gradual increase in the CR (which is not localized as pitting) as the concentration drops.

An alternative system for describing inhibitors is to indicate the environment in which they operate. Typically, a clear distinction exists between CIs for acidic or for near-neutral conditions, as protection mechanisms are usually quite different for these two types of environment. These differences are revealed for substrates immersed in aqueous solutions in the next two subsections.

#### 4.25.3.1 Corrosion Inhibition in Aqueous Acidic Solutions

In sufficiently acidic conditions, the primary corrosion reactions are:

Often these reactions take place in the absence of any significant surface films (oxides, hydroxides, or salts) on the metal, due to the solubility of such layers

at low pH. CIs for this situation are normally of the adsorption type, that is, they form a 2-D monolayer/submonolayer adsorbed directly onto the metallic substrate. Typically, organic molecules are employed,<sup>14</sup> although strongly adsorbing inorganic species such as iodide are also effective in reducing CRs in acidic conditions.<sup>15</sup> A few examples of the many organic molecules employed as CIs are depicted in **Figure 3**.

A variety of factors influence how effectively an organic adsorption CI protects a substrate. Two of the most important parameters are the strength of substrate bonding, and the fraction of the surface covered. Normally, increasing either of these quantities will improve the inhibitor performance, or, more quantitatively, inhibitor efficiency (IE). IE, which is a general term used for all inhibitors, is defined as:

$$IE = \frac{CR_{unhib} - CR_{inhib}}{CR_{inhib}} \times 100 \quad [2]$$

where  $CR_{unhib}$  is the uninhibited CR, and  $CR_{inhib}$  is the inhibited CR.

Concerning substrate bonding of organic CIs, it is useful to consider the molecule/ion to be constructed from a tail group that is normally hydrophobic and a head group that binds the molecule to the surface. As to the precise nature of the surface bonding, it is convenient to divide it into two distinct types, namely electrostatic and covalent. The former interaction arises due to attraction between the ionic charge or dipole on the CI species, and the electrical charge at the metal–electrolyte interface. The second type of bonding, covalent, involves electron transfer/sharing between the CI and the surface.

Electrostatic substrate bonding is most commonly exhibited by CIs having the formula  $NR_4^+X^-$ , with the cationic fragment acting as the primary inhibitive species. The simplest of these molecules are N-alkyl quaternary ammonium salts, for which the R groups

are alkyl chains ( $C_nH_{2n+1}$ ) of various lengths. Methyl groups are usually present to facilitate surface binding (head group), together with longer chains (tail group) oriented toward the corrosive solution. Clearly, the net charge at the substrate surface must be negative to enable  $NR_4^+$  adsorption, and these species may either bond directly to the hydrated metal surface or through negatively charged adsorbed species (e.g.,  $Cl^-$ ,  $SO_4^{2-}$ ).<sup>16</sup>

Covalent substrate bonding of organic CIs occurs through electron-rich head groups. Most often they are nitrogen or sulfur (or other Group V/VI elements) containing functional groups, although  $\pi$ -electron systems (e.g., C–C triple bonds and aromatic rings) are also effective. The bonding strength exhibited by the head group is determined by its electron density and polarizability, that is, the degree to which electrons can be donated to the substrate. These attributes depend not only on the identity of the functional group itself, but also upon the overall structure of the inhibitor molecule. For example, it has been shown for a number of aromatics that addition of ring substituents modifies inhibition performance.<sup>17,18</sup>

Turning to the surface coverage of an organic CI, usually this is related to its concentration in solution by standard adsorption isotherms. For example, the Langmuir isotherm relates the fraction of surface covered relative to a full monolayer ( $\theta$ ) to bulk solution concentration ( $C$ ) by:

$$\theta = \frac{KC}{1 + KC} \quad [3]$$

where  $K$  is a constant. On the basis of this expression, increasing bulk solution concentration will lead to greater surface coverage, as shown in **Figure 4**. Furthermore, assuming that corrosion only occurs on inhibitor free surface, IE (%) may be obtained from

$$IE = 100 \times \theta \quad [4]$$

Thus, increasing bulk solution inhibitor concentration will lead to more effective inhibition, albeit with

**Figure 3** Examples of lower molecular weight organic CIs.

**Figure 4** Plot of fractional surface coverage and corrosion rate as a function of bulk solution corrosion inhibitor (CI) concentration. Curves have been obtained using the Langmuir adsorption isotherm.

diminishing returns for increments at higher concentrations due to the nature of the Langmuir isotherm. However, this expression for IE and  $\theta$  is often not strictly valid. On the one hand, the CR of inhibitor-covered parts of the substrate may not be zero, but rather just significantly reduced. Furthermore, full monolayer coverage may not be required to maximize corrosion suppression, if the inhibitive species preferentially adsorbs at electrochemically active sites (anodic or cathodic). It has also been reported that in certain cases CIs work better at lower coverage than at higher coverage (see, e.g., Singh).<sup>19</sup>

Of course to curtail corrosion, adsorbed organic monolayers/submonolayers must not only be present but must in some way retard the rate of the anodic and/or cathodic corrosion processes. The inhibitive species may entirely cover the surface, but still preferentially interfere with only one of the half reactions. It is, in principle, relatively straightforward to differentiate between an anodic and a cathodic inhibitor by measurement of variation in corrosion potential with time upon addition of the inhibitor. Thus, if the corrosion potential increases (decreases) then the CI is anodic (cathodic), while little change indicates a mixed inhibitor. Further mechanistic insight is not obtainable from a study only of the potential shift. However, more detailed investigation may be carried out by potentiodynamic polarization, along with surface analysis techniques. There are a number of proposals for how an organic CI may function in acidic solution, including:

*Reaction site blocking* – prevents bound metal atom(s) from taking part in corrosion reactions.

*Formation of diffusion barrier* – restricts diffusion of ions/molecules to/from metal surface. More likely to be operative for larger CIs (e.g., long hydrocarbon chain tail groups), or for alkynes that polymerize on the surface forming a blocking film.

*Participation in electrode reactions* – interferes with usual reaction pathway. A diagram indicating how an inhibitor might modify the anodic dissolution mechanism is displayed in [Figure 5](#).

#### 4.25.3.2 Corrosion Inhibition in Aqueous Near-Neutral Solutions

In aqueous near-neutral solutions, the anodic corrosion reaction remains metal dissolution, but the primary cathodic reaction becomes:

**Figure 5** A diagram suggesting how a CI may interfere with anodic metal dissolution, slowing down this reaction by forming an alternative intermediate surface complex.

for aerated solutions (as illustrated in [Figure 1](#)). Also, unlike at low pH, the anodic/cathodic reactions usually occur in the presence of surface films (oxide, hydroxide, or salts). Under these conditions, CIs are typically of the film-forming variety. Typically, they are identified as being either anodic or cathodic, since these two types function rather differently, interfering with anodic metal dissolution and cathodic oxygen reduction, respectively. Inhibitor additions to deaerated solutions are not considered here, as CRs are usually sufficiently low (see previous section).

Anodic inhibitors for aqueous near-neutral solutions, sometimes known as passivating inhibitors, control the anodic dissolution of metals by inducing formation of a passive oxide film on the metal surface (typically of nanometer thickness). Their action is substrate specific, that is, an effective inhibitor for one metal is unlikely to be effective, or may even aggravate corrosion, for another metal. For carbon steels, which are of greatest interest practically, anions of various weak acids are effective, including chromate, nitrite, molybdate, and benzoate.

These anodic inhibitors can be further classified as oxidizing or nonoxidizing, depending upon whether or not dissolved oxygen is required for their operation. Chromate and nitrite are both oxidizing inhibitors, whereas molybdate and benzoate are nonoxidizing. Given the low CRs normally encountered in  $\text{O}_2$  free near-neutral aqueous solutions, this division may appear to be of little use beyond academic interest. However, the employment of oxidizing inhibitors can prevent corrosion in areas exhibiting depleted dissolved  $\text{O}_2$  concentration (e.g., in a crevice) in otherwise aerated systems.

Concerning performance of these anodic inhibitors, in contrast to the adsorption inhibitors for acidic solutions, CR does not vary smoothly with

concentration. Instead, there is an abrupt decrease in CR at a critical concentration ( $C_{\text{crit}}$ ), as illustrated schematically in Figure 6. The numerical value of  $C_{\text{crit}}$  is dependent upon the identity of the inhibitive species and substrate, as well as other environmental variables. For example, greater aggressive ion concentrations (e.g.,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ) usually increase  $C_{\text{crit}}$ . Typically, above  $C_{\text{crit}}$  the corrosion remains minimal and approximately constant, although some studies have shown a return to larger CRs at higher inhibitor concentrations (see, for example, Kolman and Taylor).<sup>20</sup> These inhibitors should also be labeled as dangerous, due to the sudden increase in CR below  $C_{\text{crit}}$ .

The existence of a  $C_{\text{crit}}$  for the onset of effective inhibition can be understood from the  $E$ -log  $i$  diagram shown in Figure 7. This plot is typical of

**Figure 6** A schematic plot of corrosion rate versus inhibitor concentration for an anodic passivating inhibitor.  $C_{\text{crit}}$  is indicated.

**Figure 7** Schematic  $E$ -log  $i$  diagram for carbon steel in aerated, neutral solution. Red (blue) lines are anodic (cathodic) curves. It illustrates what happens to the corrosion rate as the concentration of anodic Cl is increased in steps ([1]→[2]→[3]). On going from [1]→[2] the corrosion rate stays the same ( $i_{\text{corr}}$ ), but further increasing [Cl] to [3] leads to a huge drop in corrosion rate ( $i'_{\text{corr}}$ ) with the metal entering the passive region.

carbon steel in aerated near-neutral aqueous solution, that is, the cathodic curve displays a limiting current density ( $i_L$ ), and the anodic curve displays active and passive regions. As illustrated, increasing the inhibitor concentration results in a decrease in the critical current density ( $i_{\text{crit}}$ ) required for passivation. However, spontaneous inhibitor induced passivation ( $i_{\text{corr}} \rightarrow i'_{\text{corr}}$ ) is only achieved once  $i_{\text{crit}} < i_L$ , which requires a sufficient concentration of inhibitor (i.e.,  $C_{\text{crit}}$ ). Thus, there is a sudden onset of effective inhibition at a  $C_{\text{crit}}$ . The plot also indicates that there is sharp increase in the corrosion potential upon passivation, which is consistent with experimental studies.<sup>21</sup> It should be noted that some CIs (e.g., nitrobenzoate) can also increase  $i_L$ , enabling passivation to occur even with relatively large values of  $i_{\text{crit}}$ .

Concerning the precise mechanisms by which these anodic inhibitors induce passivity, limited real insight has been gained to date, although there is a great deal of speculation. Even the composition and structure of the passive films are not clear in many cases, which is essential input for nanoscale mechanistic understanding. However, CI roles likely include one or more of the following:

- catalyst for the formation of a passive film;
- reagent for the formation of a passive film;
- plugging active pores in an existing film with insoluble compounds so as to induce passivity;
- preventing the adsorption of aggressive anions; and
- reducing the rate of dissolution processes.

Cathodic inhibitors for aqueous near-neutral solutions typically reduce the rate of cathodic oxygen reduction by precipitating out an insoluble surface film, which restricts oxygen diffusion to the metal surface. Often, but not always, the films are rather thick (approx. 100 nm–few mm), and form largely independently of substrate identity. To be protective these layers must adhere well to the surface and have low porosity/permeability, as well as lack electronic conductivity, otherwise the cathodic reaction would occur on the surface of the film.

The prototypical film-forming cathodic inhibitor is a soluble salt containing, for example,  $\text{Zn}^{2+}$  cations, that results in the formation of a relatively insoluble, electrically insulating  $\text{Zn}(\text{OH})_2$  film with precipitation driven by the local rise in pH at a cathode. Importantly, and contrary to some perceptions, chromate ion, as well as being an anodic inhibitor at higher concentration, also acts as an extremely effective cathodic inhibitor at lower concentration, due to surface reduction of the  $\text{CrO}_4^{2-}$  anions to form highly insoluble  $\text{Cr}(\text{OH})_3$ .

**Figure 8** Schematic  $E$ - $\log i$  diagram for carbon steel in aerated neutral solution, illustrating the effect of increasing the concentration of a film-forming cathodic Cl. Red (blue) lines are anodic (cathodic) curves. As the concentration increases ([1]→[2]→[3])  $i_L$ , and thus  $i_{\text{corr}}$ , decreases.

Other species that can act as cathodic inhibitors include phosphonates and orthophosphates.

In contrast to anodic passivating CIs, there is no  $C_{\text{crit}}$  for cathodic inhibitors, rather the CR gradually reduces as its concentration increases. Again, this trend may be understood from considering changes in  $E$ - $\log i$  curves as a function of inhibitor concentration. As illustrated in **Figure 8**, increasing the cathodic inhibitor concentration reduces  $i_L$ , since in an aerated near neutral solution, it is determined by the transport of oxygen to the surface. As, under these conditions,  $i_L = i_{\text{corr}}$ , the CR also decreases.

#### 4.25.4 Final Remarks

In the previous subsections, we have provided an introduction to CAR and PBI under typical conditions. No attempt has been made to give a complete review of the considerable volume of knowledge and ongoing research in this area. For example, we do not make specific mention of volatile CIs, although they can be an effective adjunct to CAR for various storage and packaging applications.<sup>7,22</sup> We have also restricted ourselves to the effect of a single inhibitive substance, whereas in many cases a mixture

of inhibitors is used, which can display synergistic behavior. However, we believe we have provided enough information so that readers new to this area have sufficient insight into the basics of the following chapters in this section.

### 4.26.1 Introduction

Chemical treatments are employed in many industries to control various corrosion and operational problems. The oil and gas production and refining industries use 'treating' to describe the injection of corrosion inhibitors, biocides, scale control chemicals, oxygen scavengers, etc. into process streams, produced fluids, and hydro-test waters with the objective of mitigation of corrosion risks from carbon dioxide, hydrogen sulfide, oxygen, and bacteria. Treatment success, both technical and financial, requires selection of suitable chemical packages along with control of dose rate to achieve the required concentration in the process stream plus regular monitoring of physical assets, including injection equipment to ensure optimal control of the management system performance. Details of the role of corrosion management in oil/gas production from concept design to operations is provided in a separate chapter of this volume<sup>1</sup> and provides a wider context of the use of treating as part of the strategic and tactical requirements for oil field assets.

Corrosion in petroleum industry equipment is controlled by fluid chemistries, water content, pressures, temperatures, and flow conditions that are in turn determined by past geological conditions in oil/gas reservoirs, the rate of extraction, and use of injection water for enhanced recovery. Stable chemical equilibria are disturbed as reservoir fluids are extracted and may result in increased scaling tendency and even enhanced hydrogen sulfide concentrations in produced fluids. Exported crude oils may contain sulfur compounds and other contaminants that cause corrosion under high temperatures found in refinery operating conditions.

Reservoir fluids contain hydrocarbon phases, gases such as methane and ethane, and oils of varying composition depending on the age/type of formation and original organic material source. Other organic reservoir components, such as acetic acid, often accelerate corrosion, although they can also lead to improved oil wetting properties decreasing corrosion rates due to an increase in oil wetting of metal surfaces. Formation waters, the aqueous/brine phase in the reservoir, often contain dissolved salts, such as calcium carbonate, barium sulfate, sodium sulfate, and sodium chloride. Chlorides and sulfates can cause pitting corrosion,

whilst some dissolved salts (such as calcium carbonate/barium sulfate) may give rise to scaling conditions in some equipment. The major corrosion constituents are the acidic gases, carbon dioxide, and hydrogen sulfide that dissolve in both the oil and water phases, but cause corrosive electrolytes when dissolved in the water phase.

Overall corrosion reactions can be summarized by the following reactions.

For CO<sub>2</sub>:

For H<sub>2</sub>S:

For CO<sub>2</sub>, corrosion damage is typically seen as metal wall thinning and shallow pitting. Under high velocity conditions, deep elongated 'pits' may be observed; an erosion type of attack sometimes referred to as flow assisted localized corrosion. Iron carbonate corrosion products precipitate as semi-protective films or scales that assist in the control of CO<sub>2</sub> corrosion.

For H<sub>2</sub>S, the low solubility of iron sulfide results in the formation of black corrosion product films that are more effective at protection than iron carbonate films, particularly at higher H<sub>2</sub>S concentrations. However, the film is an efficient cathode, which can lead to intense pitting of unprotected areas. Hydrogen sulfide may also cause hydrogen damage in susceptible steels (the iron sulfide film causes atomic hydrogen produced in the corrosion reaction to diffuse into the steel). Typical hydrogen damage of susceptible steels includes embrittlement, hydrogen induced cracking (HIC), hydrogen blistering, and sulfide stress cracking.

Physical changes will also occur as produced fluids undergo pressure decrease when they rise up production tubulars, through well head/choke valves, pass along flow lines and manifolds and through gas-oil separation plant/equipment. Pressure decrease in the tubulars/reservoir to below the bubble point of the hydrocarbon gas leads to large increases in gas volumes leading to bubbly flow and even to the erosive conditions of slugging flow, [Figures 1 and 2](#). In addition, the combination of temperature and pressure decreases may cause deposition of scales, and lead to underdeposit corrosion. Corrosion

**Figure 1** Erosion corrosion of a tubular (mesa corrosion).

**Figure 2** Erosion downstream of a tubular joint in a sour system.

processes, [Figure 3](#), and bacteria present under deposits are difficult to treat because chemicals cannot easily diffuse through the scale or sludge found at the bottom of pipelines and process vessels; these deposits include mill-scale deposits, loose scale crystals/corrosion products.

In many applications, corrosion control is only one objective since control of scaling/microorganisms/fouling in downhole/field/refinery applications may be of equal or greater importance. Production economics, including factors such as plugging of reservoir strata/the hazard from a build-up of radioactive strontium scale in process plant, or microbial contamination including 'souring' of a reservoir or fouling of equipment may be of greater specific concern than that of corrosion. The majority of corrosion observed in pipelines is at the 6 o'clock position due to water drop out and deposits with corrosion, the oil

**Figure 3** Pitting corrosion found under deposits in a pipeline.

and gas phases at the upper sections is normally assumed to be 10% of the bottom water wet section. However, it has been found that with wet gas lines/lines containing glycol/methyl ethyl glycol (MEG) that is pH stabilized, the concentration of acetate from the formation water will affect the concentration of acetic acid in condensed water in the top of the line. At too high a pH, the stabilized MEG may also give precipitation of  $\text{CaCO}_3$  and  $\text{MgCO}_3$ .

In general, corrosion is often a life limiting factor for equipment, particularly c-steel constructions, and corrosion inhibition is required to ensure the design/operation life is achieved. This also means that clean surfaces, free from deposits, biofilms, and nonprotective scales are needed so that treating chemicals are able to diffuse to and adsorb on surfaces. Ideally, the metal surface should be free from mill-scale at start-up, and chemical (acid) cleaning may be used as part of the commissioning process especially for welded vessels fabricated from corrosion resistant alloys. Pipelines with their large surface areas can produce significant quantities of sludge during the first years of operation as the air formed mill-scale produced during line steel manufacture is progressively replaced by iron carbonate/iron sulfide. In many cases, the sludge build up prevent a cleaning pig run. Also, iron sulfide is pyrophoric giving rise to disposal issues. A preferred option is to sweep blast the pipe internal during the shop application of the external coating process.

The general term chemical treating includes:

- **Control of corrosion of metallic components** by corrosion inhibitors, particularly c-steel and low alloy fabrications, such as lines, vessels, columns, heat exchangers, storage tanks, and in hydrotest fluids, but can also include corrosion resistant materials when acid treatments are employed for descaling equipment, acidizing rock formations, postfabrication cleaning, and repassivation.
- **Control of biological growth** to minimize biofouling and microbiologically induced corrosion (MIC) during hydrotest and operation.
- **Control of scales** by scale inhibitors to prevent plugging of pores in strata, blocking of lines and equipment, decrease of heat transfer at heat exchanger surfaces.
- **Control of fouling** by dispersion, sequestration, chelation, and detergents to minimize formation of sludge/precipitates/deposits in lines and equipment.
- **Control of wax** precipitation in production equipment and reservoirs.
- **Control of dissolved oxygen** by oxygen scavengers in hydro-test treatments and downhole water injection systems.
- **Control of emulsions** in oil–gas separation equipment by emulsion breakers as an aid to oil/water separation processes, also includes antifoam and antisludge agents.
- **Control of pH** by caustic injection into condensate and MEG/hydrate control chemicals.

Typically, the chemicals employed have surface active functional groups containing sulfur or nitrogen (e.g., amines, amides, imadazolines, quaternary ammonium salts), that are able to adsorb onto a metal surface and displace water, modify a growing salt crystal, or kill/restrict bacterial and fungus growth. Often, several chemicals are added to a system due to different problems. As well as providing their specified functionality they may also affect the interfacial conditions between liquid phases. For example, some surface active chemical mixtures may produce stable oil in water or water in oil emulsions (by micelle formation) that often result in down stream problems, including foaming and formation of tight emulsions. Other surface active chemicals are able to destabilize water in oil emulsions (emulsion breakers) or oil in water emulsions (reverse breakers), and these are employed to improve the separation processes in production equipment.

In practice, treating must be viewed as part of an organization's strategy to mitigate the effects of

corrosion and enhance system performance. Successful management of the treating process is one of the primary aims of a corrosion team. Such teams may comprise various specialists including a corrosion engineer, chemist, biochemist, as well as production, maintenance personnel who have responsibility for the dosing and repair of injection systems. Effective chemical treating requires that ownership of the process and its boundaries must be clearly defined as part of the asset management structure. Typical duties involve selection, testing of chemicals, dosing, and monitoring, with reporting and decision making being key elements in the management process.<sup>2</sup> Most oil/gas production and refinery systems would be unable to achieve economic viability without chemicals such as inhibitors to control erosion–corrosion produced by multiphase slugging flow in pipework or filming amines as used in column overheads/condensers in refineries. The market for these chemicals is estimated at 3–6% of operational costs, of the order of millions of dollars per year.<sup>3</sup>

**Section 4.26.2** of this chapter introduces some common themes, basic concepts, terminology, and issues relating to the use of chemicals, injection equipment, and monitoring. These include batch treatments of lines with corrosion inhibitors, and biocides, where a slug of chemical trapped between two pigs/spheres is employed, or when a scale control–corrosion inhibition ‘squeeze treatment’ is used downhole. Continuous inhibition is generally preferred in fluids with a high water content, such as treatment of multiphase fluids/water lines.

Corrosion inhibitors are addressed in **Section 4.26.3**, including the impact of local conditions, such as fluid composition, throughput, and water cut, on the type of inhibitor package employed. **Section 4.26.4** considers the control of scale and deposition of fouling deposits. Control of bio-fouling and MIC, including monitoring and serial dilution, is outlined in **Section 4.26.5**. This chapter concludes with management aspects of treating processes.

## 4.26.2 Background

### 4.26.2.1 Treating Terminology

Formulations of vendor chemical treatment packages are commercially confidential with respect to the details of the type of compounds employed, although general information on the generic chemicals used (e.g., amine, quaternary amine) are provided together with data sheets on the chemical analysis performed,

for example, UV/IR spectroscopy, that is then used for QA/QC purposes. The packages are designed for particular applications and specific environments that are typically characterized by the process fluid water content or water cuts for crude oil lines/gas phase applications. Thus, the terms typically employed include: *water soluble* (clear solutions), *oil soluble* (clear solutions), *oil or water dispersible* (cloudy solutions), *oil and water insoluble* ('gunkers'), and *gas phase* (low volatility/filming inhibitors).

Treating packages not only contain active inhibitor compounds but also contain additives that assist by providing solubility and dispersibility, that is, surfactants and demulsifiers that aid performance in the field. For example, dispersibility of an oil soluble inhibitor is increased by blending it with a surfactant that assists dispersion of oil soluble inhibitors into both the oil and water phases. An increase in emulsion tendency, formation of micelles, or microemulsions can present operating problems in separation equipment, and some corrosion inhibitor–biocide mixtures can produce emulsions in water–oil systems that are very hard to break. A demulsifier may, therefore, have to be added into the processing train to help oil and water separate. The emulsion tendency is a chemical's ability to disperse one liquid phase into another liquid phase. Solvents prevent separation of active ingredients, make chemicals less viscous for injection into the production system, and maintain the chemical in liquid form during storage. Solvents also lower the pour point, the minimum temperature at which the chemical remains a liquid.

The solubility of a chemical is the ability to dissolve in solution, but for compounds with limited solubility, the degree of dispersability is used. For example, some treating chemicals are not fully soluble in either the oil or water phases and must be dispersed largely in one phase. Oil soluble–water dispersible inhibitors readily mix with most crude oils and have various degrees of dispersibility in fresh, brackish water, or brines. Dispersibility helps inhibitors to be carried by fluids to the wet metal surfaces where they absorb, displace water, and form oil–wet films that resist corrosion. Water soluble corrosion inhibitors form inhibitor films that are not as persistent as the oil soluble corrosion inhibitor films, hence continuous injection is almost always needed for effective corrosion control in fluids with a high water content–high water cut.

Surfactants are added to corrosion inhibitor packages to help clean metal surfaces. However, a major factor during operation is that preexisting air formed iron oxide films are progressively replaced by reaction

with  $\text{CO}_2/\text{H}_2\text{S}$  containing fluids. This means that large quantities of mill scale will be lost during the first few years of operation, particularly in large diameter, long distance pipelines leading to significant deposits/sludges of mixtures of oxides, carbonates, and sulfides. The maintenance of a clean surface from the start requires regular cleaning pig runs, a crucial procedure in some pipelines. Clean metal surfaces increase the effectiveness of almost all corrosion inhibitor treatments. In some equipment fabricated in corrosion resistant alloy, a precommissioning cleaning treatment followed by repassivation may be advisable before the introduction of process fluids.

Water-in-oil oilfield emulsions are droplets of water dispersed in oil or condensate. In low water cuts, water droplets become emulsified in oil due to mixing energy as fluids are produced from a formation, and are further mixed at valves and chokes. Surfactants will enhance this process, and may come from the crude oil or be introduced as part of the treating package. Emulsions may start to break down within a pipeline and this process is needed to achieve the oil–water separation process. Three steps are involved: flocculation, coalescence, and settling, see [Figure 4](#). Flocculation is the process in which water droplets gather into groups. The droplets are surrounded by surfactant films that keep them apart. Coalescence is the process in which the surfactant film breaks and allows a group of droplets to become one larger droplet. The larger droplets settle to the bottom because water is heavier than oil. These processes are responsible for the progressive water drop out at low spots in lines as both temperatures decrease away from the mixing at the well head valve but also as water cuts increase in produced fluids. Emulsions are also created when the crude is washed to remove salt at the refinery. Given enough time, almost any emulsion will separate into oil and water phases. However, some emulsions do not separate, due to stabilization by fine solids like clays and iron sulfide.

Demulsifier chemicals, often called emulsion breakers, are continuously added to emulsion streams to speed up the separation process. Demulsifiers must thoroughly mix with the emulsion to work properly. Oil field separation vessels are added to production systems to allow efficient oil–water separation after demulsifier treatment. Demulsifiers or antifoam agents are sometimes added to organic inhibitors to prevent the formation of stable emulsions.

In oil field operations, water that has been separated from oil will contain some emulsified droplets of oil. These types of emulsions are called 'reverse

emulsions' or oil-in-water emulsions. The most common causes of reverse emulsions are the improper use of an oil demulsifier, excessive demulsifier treatment, or improper sizing or operation of water separation vessels. Removal of oil from water is often required to meet disposal regulations. Reverse emulsion breaker chemicals are added to water to gather or flocculate the oil droplets into larger droplets. Larger droplets of oil will float to the top of the water. Reverse emulsion breakers must thoroughly mix with the water so it will contact the oil droplets. Provision for injection of chemicals at process plant has to be made both for emulsion control and also for inhibition of export lines and water return lines, **Figure 5**.

#### 4.26.2.2 Field Applications

Treating chemicals can be injected either continuously or in batches, depending on the application, system

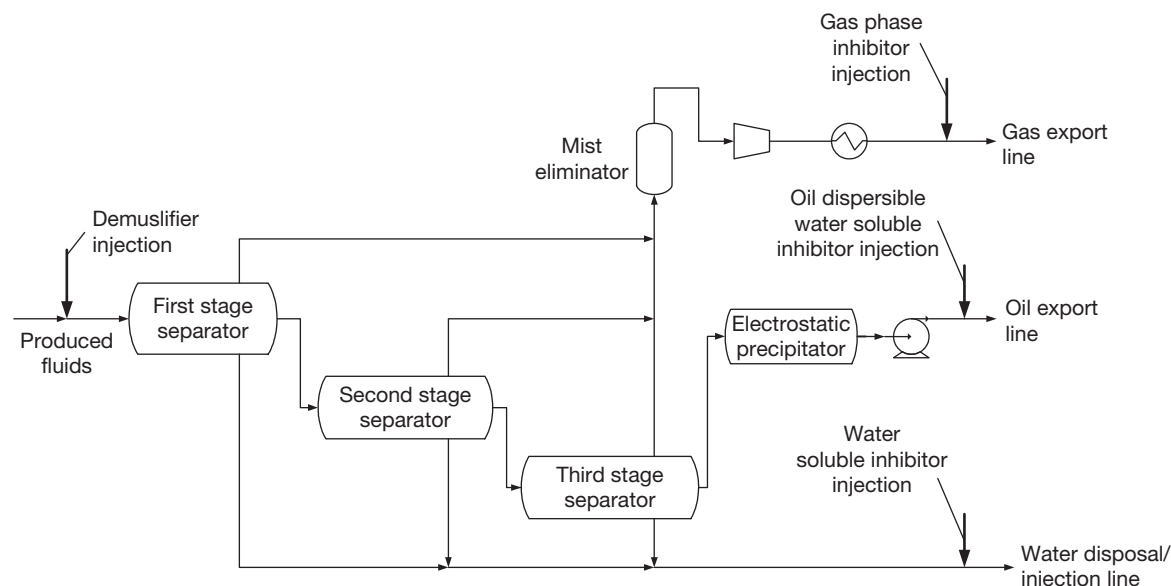

operating conditions, and fluid compositions, as well as performance versus costs. Continuous injection is generally preferred for aqueous fluid systems and multiphase fluid lines, particularly with high water cuts, and the gas phase of wet gas lines. Batch treatment is sometimes used for downhole treatments if technical or economic considerations preclude continuous injection. This may involve a 'squeeze treatment' in a similar manner to an acidizing treatment of a rock strata, but the aim is to allow inhibitor to slowly desorb from the strata back into produced fluids. Batch treatment is also used in special cases where a slug of biocide is trapped between two scraper pigs or spheres for application of a persistent inhibitor onto the surface of wet gas lines.

##### 4.26.2.2.1 Continuous treatments

Continuous dosing in high water content systems is typically employed for corrosion inhibition, scale inhibition, oxygen scavenging, and to break emulsions.

**Figure 4** Water in oil emulsion leading to water drop-out in lines.

**Figure 5** Typical chemical/inhibitor injection locations.

Continuous inhibition is a preferred method of application, particularly for wet systems, and where erosion–corrosion is anticipated. It can be used for downhole and topside equipment, including wellheads, separation facilities, flowlines, pipelines, etc. In processing trains, the inhibitor may be carried mainly by one stream (usually the separated water) and further continuous injection of an inhibitor into the other streams (exported gas and oil phases) may be required after separation. Continuous injection of gas phase inhibitors is also used for lines and equipment, see **Figure 6**.

The injection location is usually as far upstream as practicable to enable the inhibitor to reach as much of the equipment surface as possible. Common injection points in the field include: (1) downhole, (2) at the wellhead, (3) individual flow lines, (4) manifolds/gathering lines, trunk lines, separation plant, and (5) export lines. One concern is that many chemicals are corrosive when concentrated and can cause damage around the injection point, regular inspections are needed as recommended in *API 570 Inspection, Repair, Alteration, and Retesting of In-Service Piping Systems* to prevent failures of the type shown in the figure. Such failures have also been responsible for refinery fires, for example, Ras Tanura and South Humber, that resulted in significant financial/production losses, see **Figure 7**.

**Figure 6** Chemical injection into line/well.

In practice, down hole injection is difficult and prone to problems as liquid inhibitor has to be passed down a thin ‘spaghetti’ tube positioned in the annular space between the casing and the tubes. The inhibitor then goes through a valve into the tube just above the packer. All equipment below this injection point is not protected by inhibition and should be fabricated from corrosion resistant materials. Gas phase inhibitors used in gas lift operations are typically introduced under pressure down the annulus. In many cases, the flow conditions and differences in metallurgy between tubes (seamless/pierced billet) and flow lines (welded rolled plate) means that the down hole may be less of a concern and, therefore, the inhibitor is often added at the well-head.

Types of injection pumps include pressure injection systems (use of a nitrogen pressurized vessel with gravity feed), metering pump injection (positive displacement where a varying stroke length or varying speed controls the pump flow rate), flow proportional injection (produced fluid flow rate controls the injection rate, the pump is stopped when production stops). In high risk systems, a back-up pump is vital with shut-off alarms to increase reliability. Standard skid mounted equipment is used whenever possible to reduce costs and increase reliability. The supplier of the inhibitor injection system should provide

**Figure 7** Failure of line at injection point. *Corrosion Threats Handbook – Upstream Oil and Gas Production*; Energy Institute of Oil and Gas: London, 2008.

evidence, in the form of field experience or a component reliability analysis, that the required up time/inhibitor availability can be achieved.

Continuous corrosion inhibitor treatment often begins with a high concentration of chemical that ensures rapid development of an inhibitor film on all metal surfaces. After the high initial concentration, a lower concentration of inhibitor is injected to maintain the bulk fluid concentration needed to repair the adsorbed inhibitor film.

The advantages of continuous treatment are:

- It supplies chemical at all times.
- It is the most cost-effective method to treat many systems such as pipelines, process lines and equipment, and cooling water systems.
- The chemical injection rate may be optimized to control operating problems.

The disadvantages of continuous treatment are:

- Chemical injection pumps require a reliable power source.
- Chemical injection pumps must be periodically monitored and maintained.
- Chemical drums/tanks that supply chemical injection pumps must be filled periodically.

#### 4.26.2.2.2 Batch treatments

Batch treatments are typically employed for biocide treatment of seawater lines and periodic inhibitor dosage of wet gas lines where there is a risk of top of the line corrosion in stratified flow, or where a highly persistent treatment is required to provide protection for 2–3 months. The slug of concentrated chemical is trapped between two gel pigs/spheres/product separating pigs, see [Figure 8](#), and the line pressure is used to transport it through the line. The time of contact of the chemical with a section of the pipe wall is determined by the length of slug and flow rate.

Batch treatment is sometimes used down-hole when technical or economic constraints preclude continuous inhibitor injection either by application of a persistent corrosion inhibitor onto tubular walls or more usually by means of a squeeze treatment. The persistency of batch inhibitors needs to be tested in the laboratory and verified in the field to ensure batch treatment viability.

Squeeze treatment uses the producing formation as a chemical reservoir with the aim of providing a dose similar to continuous treatment, see [Figure 9](#). In squeeze treatments, a large volume of corrosion inhibitor/scale control inhibitor is pumped down the

**Figure 8** Gel pigs, spheres, and product separating pigs employed to trap a slug of treating chemical.

**Figure 9** Schematic of squeeze treatment.

tubing with enough overflush to force inhibitor into the producing formation. The inhibitor adsorbs onto the formation and is slowly produced back from the formation. A successful squeeze treatment results

in an almost continuous return of inhibitor that can last for several months. Squeeze treatments can be applied in wells with sufficient porous and permeable producing zones. The major concern with inhibitor squeeze treatment is the possibility of plugging the formation. There is little danger of formation damage when squeezing scale inhibitors. Some corrosion inhibitors cause formation clays to swell. Laboratory tests with formation core samples may be used to determine if this will be a problem.

The advantages of batch treatment are:

- Provides treatment where continuous treatment is difficult.
- Protection of pipelines operating in stratified flow, when inhibitor distribution to the top of the line cannot be ensured by other means.
- In combination with continuous inhibition for very severe or upset conditions.
- Protection of process vessels which have long residence time, and that would require impractically low continuous injection rates, for example, low temperature separator vessels.
- Batch treatments with biocides are more cost-effective than continuous treatments.
- Squeeze treatment allows continuous treatment without expensive down-hole delivery systems.
- The chemical is available where it is needed.
- Less manpower required to check on chemical treatments.

The disadvantages of batch treatment are:

- A significant portion of the chemical may be wasted.
- Corrosion and bacteria are not continuously controlled between treatments.
- Wells are taken off production for several hours.
- Squeeze treatment can plug or damage the producing formation.
- The high cost of treatment.
- The chemical returns from the formation must be monitored.

### **4.26.3 Corrosion Inhibition**

The use of inhibitors in the field and process equipment is defined in terms of the metal and the corrosive environment. Packages that protect one metal, c-steel, may not protect another, stainless steel. Similarly protection of a metal in, for example, acidic solutions ( $\text{CO}_2/\text{H}_2\text{S}$  corrosion) may not work in neutral solutions, particularly when dissolved oxygen is the

corrodant. Various commercially available corrosion inhibitor packages have been developed for use in water systems, gas systems, oil field production systems, and refineries.

#### **4.26.3.1 Inhibition Processes**

Corrosion inhibitors work by one or more of the following mechanisms: precipitated films that visibly coat and protect metal surfaces (calcium salts in potable water, zinc salts in cooling waters), passive oxides which combine with corrosion product films to protect metal surfaces (silicates and molybdates in cooling systems), and adsorbed monolayers (organic molecules in oil/gas systems). The first two mechanisms, rely on relatively inexpensive inorganic salts, are used mainly in cooling towers, boilers, and fractionation units. The adsorption type of organic inhibitor is employed in oil field systems, and to prevent overhead corrosion in some refinery units (e.g., use of filming amines) are organic inhibitors. Inorganic inhibitors are further divided into anodic and cathodic classifications that describe the polarization of electrochemical corrosion process that are modified by the inhibitor action. Organic film-forming inhibitors (amines, amides, and imadazolines) block both the anodic and cathodic processes, although most tend to mainly polarize the anodic reaction as observed by an increase in corrosion potential. Note that although cost effective water treatments typically use inorganic compounds these often are more effective in combination with small additions of organic chemicals to provide a synergistic effect.

Inhibitors for near-neutral and alkaline environments in the presence of oxygen decrease the rate of the oxygen transport/rate determining step by the formation of an electronically nonconducting film on the metal surface (cathodic inhibitors). Inhibitors for oxygen-free near-neutral solutions, as may be found, for example, in oil production, cause the steel to form or retain a protective oxide film which acts as a barrier to metal dissolution, so that the corrosion rate is now controlled by the anodic process (anodic passivating inhibitors). Anodic inhibitors effectiveness relies on maintenance of a passive oxide film on the metal surface and includes both oxidizing inhibitors (nitrite, etc.) and nonoxidizing that require dissolved oxygen (phosphate, benzoate, borate, carbonate, hydroxide, molybdate, etc.). Insufficient dosage of anodic inhibitor may cause localized corrosion (e.g., pitting).

In acid environments, both metal dissolution and hydrogen evolution reactions are under activation control and can occur in the absence of surface films of oxides or corrosion products, because of their solubility in acid. Even a small reduction in the kinetics of either process will reduce the corrosion rate. Inhibitors for acid solutions usually function by adsorption on the metal surface, and typically contain elements in Groups V or VI of the periodic table, for example, N, P, O, S, or As, which possess lone pairs of electrons which can be donated to the metal to form a chemical bond by chemisorption. The tendency is to use long chain nitrogenous inhibitors (amines) and imidazolines. Exact mechanisms are not fully understood, but chemisorption appears to occur at active sites and physisorption at the remainder of the surface. The organic inhibitor molecules can be modified to increase their solubility or dispersibility in brine. These modifications include adding more polar groups to each inhibitor molecule.

Adsorption type inhibitors usually contain N or S atoms with an attached organic chain (typically C12–18) that determine the solubility, and are usually aliphatic (straight chain) fatty acid derivatives. Most metal surface in contact with an aqueous solution is covered with adsorbed water molecules and the unshared electrons in the polar N group of the inhibitor forms a chemisorption type bond with the metal surface. Organic inhibitors also physically adsorb to the metal surface but this is weaker than chemisorption. Some molecules also have an ability to attract each other and form a 2-dimensional monolayer across the metal surface. The chemisorption bond displaces water molecules (4–8 per inhibitor molecule) and other corrosive agents from the metal surface. These processes are described by standard adsorption isotherms

(Langmuir, Tempkin, etc.) of inhibitor solution concentration ( $c$ ) versus a function of the surface coverage ( $\Theta$ ) at various temperatures. The adsorption process can be visualized as formation of covalent bond between metal and polar group along with displacement of adsorbed water molecules, nonpolar or aliphatic end of molecule orientated outwards encouraging adsorption of a hydrophobic oil layer as illustrated in **Figure 10**.

Organic inhibitors include *mono amines*, typically used in refinery overheads and hydrotest packages, *diamines*, more efficient in oil systems than monoamines, *amides*, poly ethoxylated compounds made with differing oil and water solubilities (solubility increases with amount of ethylene oxide, acetic, oleic, dimeric naphthenic, or phosphate salts), and *imidazolines and derivatives*. Most exhibit at least partial solubility or dispersibility in both oil and water.

Water soluble inhibitors are required for fresh and brine waters, typically quaternary amines, amine salts, or salted imidazolines, see **Figure 11**. Water soluble corrosion inhibitors form a protective film on metal surfaces in sweet or sour environments but the inhibitor films are not as persistent as oil soluble corrosion inhibitor films. These tend to desorb at high temperatures and may salt out (lose solubility) in brines that contain a high concentration of total dissolved solids (TDS). Continuous treatments are almost always needed for effective corrosion control.

Oil soluble inhibitors tend to be long chain primary amines, imidazolines, fatty acids, and phosphate esters. These packages are also more effective at higher temperatures and high velocities.

Oil soluble-water dispersible inhibitors are normally used in oil wells and gas condensate wells and readily mix with most crude oils in sweet or sour

**Figure 10** Schematic of adsorption inhibitor processes.

systems. They also have various degrees of dispersibility in fresh, brackish, or brine water. Higher concentrations of water dispersible inhibitors are usually needed as production increases and water break through occurs. The inhibitors form oil-wet films that resist corrosion under most conditions.

Batch treatment inhibitors are either oil soluble or 'gunkers' in order to achieve better persistency when water-wet. In wet gas lines, continuous injection of gas phase inhibitor is often applied in conjunction with periodic batch treatment.

Gas phase inhibitors are usually low molecular weight amines that have a high vapor pressure.

#### 4.26.3.2 Inhibitor Performance

The performance of inhibitors is often defined by their efficiency based on the corrosion rate with

and without inhibition, with the input data being obtained from corrosion coupons, and/or portable instrumentation (electrical resistance/electrochemical polarization resistance) using probes inserted into the process line or test solution. Inhibitor efficiency can be calculated from the following expressions:

For weight loss:

% Inhibitor Efficiency

$$= \left[ 1.00 - \frac{\text{Weight loss (with inhibitor)}}{\text{Weight loss (without inhibitor)}} \right] \times 100$$

For corrosion rates:

$$\text{Inhibitor efficiency} = \frac{\text{Rate without} - \text{Rate with}}{\text{Rate without}} \times 100$$

N.B. 100% efficiency = no corrosion, 0% efficiency = no effect of 'inhibitor.' Inhibitor efficiency is also used often as a measure of the surface coverage as illustrated in Figure 12, where 100% efficiency corresponds to a surface coverage of one, and 0% efficiency to zero surface coverage.

The graph in Figure 12 shows that for an adsorption type inhibitor the coverage (or efficiency) can be increased by increasing the bulk concentration in the fluid, and conversely, reducing the concentration reduces the efficiency. In practice, there is a balance between performance and cost but also the actual corrosion rates obtained are an important consideration. The efficiency required varies greatly from system to system. For example, pipeline designed some 25 years ago reflected a degree of conservatism and often assumed inhibitor efficiencies of 60–85%. However, improvements in vendor inhibitor formulations are based on experience at, for example,

**Figure 11** Basic structures of adsorption corrosion inhibitors.

**Figure 12** Relationship between inhibitor efficiency, surface coverage, and bulk concentration.

Prudhoe Bay from 1996 onwards shows that a field corrosion inhibitor efficiency of 98% for multiphase flow lines can be obtained. The use of an inhibitor efficiency of greater than 95% for design purposes is a high risk strategy that requires effective monitoring and corrosion management processes, but is achievable in practice. Some authors<sup>4</sup> consider 80% or 90% minimum efficiency obtained in the laboratory as a hypothetical assumption, since correctly chosen inhibitors can have efficiencies in the field of >99.9%, that is, inhibition ratios of  $10^3$ – $10^6$  (the inhibition ratio is the corrosion rate without inhibitor/corrosion rate with inhibitor). The purpose of efficiency measurement is as a tool to provide a ranking of candidate packages and is used to select inhibitors prior to field testing/application.

A second but important practical consideration is the corrosion inhibitor availability<sup>5</sup> ( $A$ ), that is the time the inhibitor is present in the system at the required dosage, where  $A\%$  = the time the inhibitor is added divided by the lifetime  $\times 100\%$ . The design corrosion allowance (CA) is then defined as:

$$CA_{\text{total}} = CA_{\text{inhibited}} + CA_{\text{uninhibited}}$$

The CA would be given by:

$$CA = (CR_{\text{inhibited}} \times A\% \times \text{Lifetime}) + (CR_{\text{uninhibited}} \times [1 - A\%/100] \times \text{Lifetime})$$

The design stage assumption is that inhibition can decrease the corrosion ( $CR_{\text{inhibited}}$ ) to between 0.1 and 0.3 mm year<sup>-1</sup>, that is, practical values that would have to be reviewed once field data trends were obtained. The availability concept emphasizes the criticality of inhibition downtime in high risk systems and uses realistically achievable corrosion rates that focuses attention on the importance of maintaining and managing the dosage/inhibitor supply chain.

Partitioning of inhibitors between the oil and water phases is also an important consideration as the practical aim is to achieve a required concentration of inhibitor in water phases where corrosion occurs. As the water cut increases during production, the inhibitor will distribute itself at different concentrations in the water and oil phases. The volume fractions of the phases are important factors in establishing partitioning between oil and water phases as the theoretical basis is given by:

If

$$C_o V_o + C_w V_w = C_t \text{ and } C_w/C_o = P$$

where  $C$  is concentration,  $V$  is volume fraction,  $w$  is water phase,  $o$  is oil phase,  $t$  is total fluids, and  $P$  is partitioning coefficient (water/oil).

Then

$$C_w = C_t P / (V_o + P V_w) \text{ and } C_o = C_t / (V_o + P V_w)$$

Some operators specify a recommended inhibitor concentration in the water phase which is a sound practical consideration. Experimental data on inhibitor partitioning is then used to estimate the necessary concentration in the total fluids for a given water cut. Thus, a preferentially water soluble component ( $P > 1.0$ ) will have a higher concentration in the water phase than a preferentially oil soluble component ( $P < 1.0$ ).

Selection of an inhibitor requires consideration of several factors:

- The nature of the operating environment and the operating conditions.
- The materials requiring protection.
- Possible interactions between chemical additives.
- The efficiency of an inhibitor.
- Possible adverse effects of inhibitor on other aspects of the operation.
- Environmental effects of the inhibitor.
- The physical properties of the inhibitor.

#### 4.26.3.3 Inhibitor Testing

A range of test procedures are available to assess inhibitor packages for various applications, including Bubble Test for initial screening, rotating cylinder electrode (RCE) for various flow conditions, segmented welds for low conductivity fluids, autoclave tests for high pressure/high temperature conditions. Such methods and procedures, along with others, have been developed over the years for assessment of oil industry inhibitors, but not all are routinely performed, rather a limited number of basic and reproducible tests have been adopted. A North Sea oil industry sponsored program of testing during the mid-1980s identified the Bubble Test, the Rotating Cylinder, and Jet Impingement as being able to provide the basis of a test protocol. The study provided statistical evidence of the reliability and reproducibility of electrochemical measurements in the establishment of corrosion rates and provided the basis of published work in this area.<sup>6,7</sup>

##### 4.26.3.3.1 Bubble test

The test is designed for rapid screening of inhibitors using brine solutions (simulated or field samples)

as the test fluid held in an easily cleaned glass vessel containing between 150 ml and 1 l of test solution. The test is carried out at room pressure (1 atm), with a sparge gas being bubbled through the solution using a mixture of a carbon dioxide/hydrogen sulfide/nitrogen concentration that simulates the field partial pressures of CO<sub>2</sub>/H<sub>2</sub>S. The vessel is sealed with water traps and purged of air prior to test solution introduction, test temperatures range from ambient to boiling. Samples of degassed crude may be introduced to form an oil layer if there are concerns regarding acetates, etc. The solution is magnetically stirred to ensure mixing but the shear stresses are low, <1 Pa.

The normal procedure is to establish a base line corrosion rate, after a few hours but often over 24 h, using standard electrodes and test probes prepared by a rigorous degreasing/abrading/cleaning procedure. The base results give the uninhibited corrosion rate and this also identifies any samples that have a poor/out of specification preparation. The inhibitor must be soluble or dispersible in both hydrocarbon and water, it is added at the required dose rate and the inhibited corrosion rate obtained typically after a further 24 h from which the inhibitor efficiency is determined.

Bubble tests are almost always the initial screening tests because they are simple, easy to carry out,

and reliable, if based on electrochemical measurements but are restricted to ~1 bar total pressure and <100 °C. They cannot reproduce high temperature–pressure systems, but nonetheless can still be an effective initial screening methods for such systems.

#### 4.26.3.3.2 RCE test/flow loops

These tests are designed to reflect actual system wall shear stresses found under stratified flow conditions in pipelines. Many studies have demonstrated the validity of the approach based on standard hydrodynamic correlations, so that suitably designed equipment will give similar results from the two methods. Both can be pressurized but the RCE is often more convenient due to ease of operation and cleaning. Electrochemical measurements are normally employed or electrical resistance measurements in high hydrocarbon systems. Measurements can be made on a cylindrical electrode that forms part of the rotating shaft, but electrode probes positioned in the wall of a cylindrical test cell can also be employed, provided the electrode is machined to the wall profile and that a relatively small annulus is used to contain the test fluid so that the flow conditions are similar on the rotating cylinder and wall.

Figure 13 illustrates typical data from a dynamic test and shows that the two types of test give

**Figure 13** Comparison of flow loop and RCE test data showing inhibitor efficiency tests and the effect of simulation of downstream of erosion pits.

compatible results provided the fluid to wall shear stresses are the same and enables pipeline conditions to be simulated. If inhibitor dose rates are sequential, the increased test can define the effect of concentration on performance. Base line uninhibited corrosion rates were established over the first 24 h, then inhibitor was injected at increasing dose levels of 10, 20, and 30 ppm. The RCE design can also be modified to assess the effect of inhibition downstream of a simulated erosion pit—local flow disturbance. The table shows the test data expressed as inhibitor efficiency as obtained from a flow loop test, an RCE, and autoclave rotating cylinder tests (higher rates) compared to efficiency under local turbulence conditions. The inhibitor did not perform as effectively under more turbulent intensity conditions.

#### 4.26.3.3.3 Inhibitor persistency

There are always times when, for some reason, inhibitor dosage ceases and it is then important that

protection persists for some time until inhibitor injection is reestablished. However, it is not a widely studied property, and therefore underestimated, particularly for high risk systems. Different inhibitors can show very different persistency as shown in Figure 14. The bubble test and jet impingement tests are employed, and by changing the fluid compositions, after an inhibitor film is first established, the persistency can be evaluated. The initial base line data and efficiency after 24 h were obtained using an RCE and inhibitor and then the persistency assessed by substitution of the inhibited test solution with fresh but already sparged fluid. The test indicates how quickly the corrosion rate returns to the original uninhibited rate. In the case of the quaternary amine package, there is a rapid increase in corrosion rate when inhibitor dosing is stopped, although complete loss of protection does not occur in the test. In the second case, the carboxylate amine, there is a good response as the inhibitor appears to be retained and redistributed on the metal surface.

**Figure 14** Electrochemical test data showing initial uninhibited corrosion rate, inhibition, and persistency check.

#### 4.26.3.3.4 Jet impingement

The test is designed to give high shear stresses, but the quantification of shear stress is not as well-established as for flow loops or the RCE. It is also possible to obtain the high shear stresses normally associated with erosion–corrosion by use of a pulsed gas bubble injection into the feed to the impinging jet.

#### 4.26.3.3.5 Inhibition of weld corrosion

This form of accelerated CO<sub>2</sub> attack is of particular concern in condensate lines and low conductivity waters. Nickel containing welds used in oil field fabrications to provide the required strength are cathodic. However, the high nickel content of the corrosion product film gives rise to different corrosion kinetics and films compared to the low alloy steel plate, which when combined with the high resistance of the electrolyte means that the normal galvanic protection derived from the weld being coupled to the more anodic parent plate does not occur and the weld may be preferentially attacked.

Some inhibitor packages can increase the rate of weld metal corrosion as they are less effective in the presence of the high nickel content corrosion product, but careful selection of an appropriate inhibitor can mitigate the problem. The test procedure is to section a weldment into five electrodes – weld metal, heat affected zones (HAZ), and parent plates and then reassemble the sections into a test electrode, [Figure 15](#). Electrochemical corrosion rates are obtained via five zero resistance ammeters each connected to an electrode segment from which the individual rates of corrosion and galvanic coupling currents can be determined, [Figure 16](#).

#### 4.26.3.3.6 Autoclave tests

These are normally the final tests to replicate field conditions as they are expensive and usually restricted to inhibitors that are expected to be effective as based on previous and simpler tests. Typically employed to assess combined high temperature–pressure conditions and may also incorporate RCE and jet impingement, as well as electrochemical monitoring. Autoclave tests can be considered as being under full system condition simulation, with the test variables, fluid chemistry, ppCO<sub>2</sub>, ppH<sub>2</sub>S, shear stress, temperature and monitoring, subject to feasibility study Wt loss, LPR, and Ceion probe.

#### 4.26.3.3.7 Compatibility

Compatibility with other production chemicals must be considered not only to control emulsions but also to

**Figure 15** Preferential weld corrosion probe and inhibitor performance test data.

prevent failures that have occurred due to loss of performance of some of the oilfield chemicals. In general, a compatibility test will be concerned with assessment of emulsion stability, where a sample of untreated degassed crude is mixed with a sample of brine (field or synthetic) to which is added a known amount of treating chemical to give a similar concentration as will be employed in the field. The mixture is shaken and the time taken for the oil/water emulsion to break is noted. The effect of treating chemical mixtures on corrosion performance is also important. In the case shown in [Figure 17](#), the corrosion inhibitor and other chemicals were found to be incompatible because of the effect of the biocide.

#### 4.26.3.3.8 Field deployment

There are many issues related to field deployment activities and the reader is referred to the *European Federation of Corrosion Document Number 39, The Use of Corrosion Inhibitors in Oil and Gas Production*<sup>8</sup> for full details. In particular, problems can include: preparation of inhibitors for injection, such as dilution and mixing, deaeration–gas blanketing; the introduction

**Figure 16** Effect of inhibitor dosing with time and increased dosage.

**Figure 17** Effect of chemical additions on corrosion.

of atmospheric oxygen into chemical storage tanks or into water used to dilute ‘neat’ inhibitor is a prime cause of problems. Many chemicals are corrosive when supplied as concentrates and the injection equipment is usually constructed from 316 stainless steel. Preparation of facilities and pipelines for inhibition; improved performance is achieved in clean systems; therefore, cleaning and descaling may be required, for example, use of specially designed, adjustable scraper pigs, provision for removal of solids at pig traps, and use of specialist cleaning contractors.

Operation and maintenance of injection equipment must be managed with overall coordination of

maintenance, housekeeping, and inspection activities allocated to a supervisor who has responsibility for updating the records; note that high corrosivity systems may require >95% up-time on injection equipment. Monitoring and inspection are key activities in corrosion inhibition management and asset integrity strategies. Regular corrosion monitoring/corrosion inspection to obtain trend data is the only means to ensure inhibition is effective. Inspection is also used periodically to ensure the integrity of production equipment, including export pipelines. Monitoring and the recording of all available parameters, including production rates, water cuts, and inhibitor consumption,

are required to ensure that the program is operated and managed correctly.

Clean metal surfaces increase the effectiveness of almost all corrosion inhibitors; consequently, an initial cleaning treatment may be advisable before the introduction of a corrosion inhibitor system. Corrosion inhibition is also less effective in old, corroded, and pitted pipelines or facilities and in systems that contain large amounts of debris. Dosages may have to be increased or the system cleaned; in some cases, a scale inhibition program may have to be implemented in addition to the corrosion inhibition program. The inhibitor may not perform as anticipated in the field or there may be poor management of the dosage leading to lower than required inhibitor availability.

#### 4.26.4 Scale Inhibition/Control

Scales, sometimes referred to as hard fouling, can plug reservoirs and equipment in production systems, flowlines, and pipelines. Scales can also affect the thermal efficiency of heat exchangers and boilers (an increase in the design fouling factor). Scaling and fouling by deposits–corrosion debris are both typically controlled by similar treating packages. The aim is to minimize operating problems (poor heat transfer, plugging) and aid corrosion control (under deposit corrosion) by use of scale control chemicals (phosphonates, phosphate esters, polymers). Note that prevention of scale formation on oil field lines may result in more fine crystals or sludges being carried downstream to oil and gas separation plants, see [Figure 18](#).

Scale can inhibit or promote corrosion. Hard, non-porous scales may sometimes protect metal surfaces from electrolytes and prevent corrosion. For example,

the addition of calcium salts helps to control corrosion ('red water' in desalination potable water) and other soft water distribution systems by deposition of calcium carbonate. Loose or porous scales can create concentration cells that accelerate corrosion in boilers, cooling systems, and production equipment. Since corrosion usually occurs under scales, particularly on heat transfer surfaces, it is better to prevent and remove a scale whether or not it protects the metal.

##### 4.26.4.1 Scale Inhibitor Application

Scale inhibitors must always be present to stop scale formation. Batch treatments with scale inhibitors are NOT effective. Scale inhibitors are usually continuously injected at low concentrations (5–25 ppm). Scale inhibitors can react with calcium and iron in produced water to form a scale. This usually occurs at the point where a concentrated scale inhibitor is added to the system. If the scale inhibitors are diluted with fresh water, this problem can be prevented. Scale inhibitors may also be injected in the middle of the flowline so they are quickly diluted.

##### 4.26.4.1.1 Scale treatment chemicals

**Inorganic Phosphates** – They contain a P–O–P group and have a tendency to adhere to the surfaces of scale crystals and prevent further crystal growth. They are effective at low concentrations: 2–5 ppm for  $\text{CaCO}_3$ ; 10–12 ppm for  $\text{CaSO}_4$ ; and >50 ppm for  $\text{BaSO}_4$ . The most common examples are sodium hexametaphosphate and sodium tripolyphosphate. Inorganic phosphates have certain disadvantages. They revert from metaphosphate to orthophosphate at temperatures above 60 °C. Reversion makes the scale

**Figure 18** Oil field scales formed in flowlines.

inhibitor ineffective. Reversion occurs slowly with age and in low pH solutions. Inorganic phosphates were used extensively before organic phosphonates, phosphate esters, and polymers were discovered. Because of the disadvantages of inorganic phosphates, organic type scale inhibitors are used more often. The organic scale inhibitors described below prevent crystal growth much like inorganic phosphates.

**Organic Phosphate Esters** – Phosphate esters have excellent scale inhibiting properties and are thermally stable up to 82 °C or 93 °C.

**Organic Phosphonates** – They are more thermally stable than phosphate esters. The reason is that the phosphorous is directly bonded to the carbon atom in phosphonate inhibitors. An example is amino trimethylene phosphoric acid (ATMP). ATMP acid derivatives are stable at all pH conditions up to 230 °C. ATMP acid derivatives are used extensively in scale inhibition squeeze programs for oil producing wells.

**Organic Polymers** – They are effective against calcium carbonate, calcium sulfate, and barium sulfate. They have excellent thermal stability. Examples of organic polymers are polymaleates, polymethacrylates, and polyacrylamides, see [Table 1](#).

#### 4.26.4.1.2 Scale control

The mechanisms of scale control are complex but include:

- Threshold inhibition (hardness stabilization) aims to prevent creation of crystal nuclei (enable scale forming salts to exist in an over-saturated form), a kinetic process that allows the creation of submicroscopic nuclei.
- Crystal modification (growth control) due to adsorption/incorporation of scale inhibitor molecules or ions, this result in decreased growth and cohesion between deposited particles.
- Sequestration (chelation), the use of chemicals that complex or chemically bond to dissolved salt ions and remove them from precipitation reactions.

- Anionic dispersion (destabilization theory), the dispersion chemical, usually a highly anionic polymer, adsorbs onto a slightly anionic scale particle and increases the charge density causing the particles to remain in suspension in the water.

#### 4.26.4.2 Scale Predictions

The tendency for a water to 'scale' is dependent on the calcium carbonate concentration (that is its 'hardness'), the pH and total alkalinity, dissolved solids, and temperature. When the solubility product of a scale forming material is exceeded, it can form a scale. The scaling tendency (the probability that scale will form) increases as the amount of supersaturation increases. Calcium carbonate forms when carbon dioxide is released from solution. This usually occurs when the pressure decreases. Calcium carbonate scale commonly forms in producing wells and associated flowlines in some fields. These scales can form in production equipment and interrupt operations. Normally, produced waters contain calcium ions ( $\text{Ca}^{2+}$ ), bicarbonate ions ( $\text{HCO}_3^-$ ), and carbon dioxide ( $\text{CO}_2$ ). When  $\text{CO}_2$  is evolved, the pH of the solution increases. The bicarbonate ions dissociate to form carbonate,  $\text{CO}_3^{2-}$ . The carbonate reacts with calcium to form  $\text{CaCO}_3$ , which precipitates as it is relatively insoluble.

The scaling tendency of  $\text{CaCO}_3$  increases as the temperature increases.

For pH between 6.5 and 9.5, the chemical equilibrium is given by:

$$\text{pH}_{\text{sat}} = (\text{pK}_2 - \text{pK}_s) + \text{pCa} + \text{pAlk}$$

A basic indicator of scaling, the *Langelier Index*:

$$\text{Ls} = \text{pH}_{\text{act}} - \text{pH}_{\text{sat}}$$

shows when  $\text{Ls} < 0$ , the water is corrosive and non-scaling and when  $\text{Ls} > 1$  it is scaling.

Chelates			X	

Another index, the *Ryzner Stability Index*:

$$Rz = 2pH_{\text{sat}} - pH_{\text{act}}$$

indicates that the solution is for  $Rz < 6$  – increasingly scaling;  $Rz > 7$  – not scaling;  $Rz > 8$  – increasingly corrosive.

In cooling waters, scale control can be achieved by modifying the pH – for example, acid dosing thereby ensuring good heat transfer in equipment but this then requires improved corrosion inhibition of the cooling water. In potable water systems, scaling on metal surfaces is desirable to reduce corrosion rates by formation of a barrier layer. Thus, if such waters do not naturally possess a scaling tendency, as determined by the Langelier Saturation or Ryznar Stability Indices, lime may be added to raise the calcium levels until calcium carbonate scaling forms on the pipe surfaces. Dezincification, that is, the selective dissolution of zinc from brass alloys used in water distribution systems, is also reduced by lime addition. It should be noted that the water output produced from a desalination plant is normally mixed with a small volume of sterilized seawater or groundwater to principally produce a palatable product. If this is done, the water may have sufficient scaling tendency without the need for further lime additions.

In oilfield systems, particularly where commingling takes place, the concern is to inhibit scale formation to prevent plugging of wells, flowlines, plant, or the reservoir. The potential of forming ‘hot’ radioactive scale is another hazard (radium related radioactivity), possibly as coprecipitants with  $\text{BaSO}_4$  scale. Contaminated equipment may require specialized handling, and this would have an impact on the maintenance cost. Applicable scale inhibitors should be applied to limit excessive scale build-up and reduce the impact of such radioactivity.

For a more complete prediction of scaling in systems and reservoirs, sophisticated codes are available based on the equilibrium chemistry of the major ionic components present in the brines/waters. Below, some of these are outlined.

**Petrotech MultiSCALE Code** – this Norwegian University code, developed with support from Statoil, Saga Petroleum, and Norsk Hydro predicts the simultaneous precipitation of the respective scaling species. The code computes the equilibrium concentrations of Ca, Sr and Ba sulfate, and Ca and Fe carbonate scales, in addition, the code predicts FeS and halite precipitation. The user can allow the program to select the ‘stable phase’ for  $\text{CaSO}_4$  precipitation or choose whether gypsum or anhydrite is to be considered.

**OKU Code** – the OKSCALE Prediction Model computes the equilibrium concentrations separately for  $\text{CaCO}_3$  and sulfates of Ca, Sr, and Ba. All the sulfates are considered simultaneously; the user can choose whether gypsum or anhydrite is to be considered. The program has been upgraded following lengthy and detailed empirical  $\text{SrSO}_4$  and  $\text{CaCO}_3$  solubility determinations conducted by the OKU research group. The program calculates  $\text{CO}_2$  fugacity either from the associated gas composition ( $\text{CO}_2$  mole % level) or from a dissolved  $\text{CO}_2$  value.

**RICE Code** – a Pitzer based model which utilizes the Peng-Robinson EOS to calculate fugacity coefficients. This model predicts the simultaneous precipitation of the respective scaling species. The code computes the equilibrium concentrations of Ca, Sr and Ba sulfate, and Ca and iron carbonates. In addition, it will predict halite, FeS, ZnS, and  $\text{CaF}_2$  precipitation.

Such scale prediction programs are not by themselves definitive, rather they give an indication that a problem may occur. The level of precipitation predicted in many cases can be higher than that observed in a system. The levels of precipitation predicted are based on equilibrium solubility data, but these data do not take into account reaction kinetics. Furthermore, prediction accuracy is not just a function of modeling limitations, much depends also on the quality of the data input. If brine compositional data is inaccurate, possibly due to poor analytical technique or more commonly due to poor sample handling, then the computer prediction data will be devalued. Often brine analysis is conducted on samples many hours after sampling, transient changes occur, and precipitates may form. Results may be reported for filtered samples, without thought for the precipitate removed. Clearly unstable species, such as  $\text{HCO}_3^-$ , should be determined on-site; dissolved  $\text{CO}_2$  levels should be determined on pressurized bomb samples.

The results of a typical PREDICTIVE study of a field whose water chemistry indicates a significant probability of barium sulfate scale when sea water injection is employed is shown in [Figure 19](#), with the likely concentrations and scaling tendency plotted against seawater breakthrough. There is also a possibility of microbiological build up as water breakthrough increases.

[Figure 19](#) illustrates the likely changes with continuing water injection leading to an increase in the barium sulfate and water profile with production time. Initially, the scaling will be calcium carbonate, but then it is the barium scale profile that predominates and the squeeze treating chemical would

**Figure 19** Predicted scaling tendency (mass and supersaturation) over the life cycle of a well described by the sea water injection), scaling and MIC profiles compared to the barium scale and water profile over the field life.

have to be changed for these new peak conditions. The MIC also reaches a peak, hence, this is the most costly period with the chemicals having to control both scale and MIC; compatibility issues would also have to be addressed. Further changes in chemicals can be anticipated later in field life.

It is important to understand that the precipitation of an insoluble salt crystal does not always result in scale deposition; much depends on the system parameters, dynamics, and the presence of crystal interacting chemistries. Precipitates (particularly if oil-wet) may to some degree be transportable. Nevertheless, scaling predictions should be used as an indicative tool to test sensitivities and estimate trends. However, careful consideration needs to be given to interpreting the outputs; generally, the predictions can be assumed to be a worst case.

Testing for scale formation is by:

- (i) Static mixing tests – NACE TM0397, 0197, 0374  
Advantage – Simple quick tests mix the waters and weigh deposits or analyze for scale species,

Ca, SO<sub>4</sub>, Ba, simple measure of efficiency.

Disadvantage – Does not evaluate crystal modifiers on an even basis.

- (ii) Dynamic tube blocking tests.

Dynamic laminar flow used to examine growth mechanisms (scale and/or microbiological fouling) using a strata core sample, temperature >100 °C possible, allows examination of systems under pressure.

#### 4.26.4.3 Squeeze Application

Core flood assessment used to determine inhibitor return profile isotherm by means of a model squeeze treatment, 'SQUEEZE V' to determine various parameters: squeeze life, concentrations, shut in period, postflush, see Figure 20. Effectively a sensitivity study but the model must be optimized after first treatment. Variations in: local temperatures, flow rates, precise scale inhibitor mechanism (precipitation/adsorption) will influence the model and actual response.

#### 4.26.4.4 Scale Inhibitor Selection

Typical program includes:

- Monitor changes in well, water composition, and physical conditions data. Carry out scale prediction modeling to assess scale risk throughout production system, surface, and subsurface.
- The scale inhibitor candidate products are tested for performance and compatibility.
- Brine/chemical compatibility, various field water/sea water ratios to test for inhibitor/brine compatibility, static inhibitor adsorption tests on reservoir core (if for squeeze application).
- Efficiency performance test.
- Static bottle tests.
- Dynamic loop.
- Thermal stability tests for application >130 °C.
- Production chemical interference tests with candidate scale inhibitor.
- Review of inhibitor performance data.
- Select product.
- Core flooding and squeeze modeling.

#### 4.26.4.5 Scale Removal

**Mechanical** – rod out the scale from heat exchangers, 'scraping'/'pigging' of lines.

**Chemical methods** – calcium carbonate is soluble in hydrochloric acid, acetic acid, formic acid, and sulfamic acid. Iron carbonate, iron oxide, and iron

sulfide are also soluble in hydrochloric acid. The HCl must contain a sequestering agent (e.g., acetic acid, oxalic acid, gluconic acid, or citric acid) to prevent precipitation of iron. Gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) is insoluble in acids. However, gypsum can be converted to another scale that is soluble in acid. Ammonium bicarbonate or sodium carbonate converts gypsum to calcium carbonate. Potassium hydroxide converts gypsum to calcium hydroxide. Both calcium carbonate and calcium hydroxide are soluble in acid. If the scales are covered by waxes, the waxes should be removed with organic solvents first. Waxes are not soluble in acids. Mechanical methods must be used to remove barium and strontium sulfate from tubes. An attempt should not be made to dissolve barium or strontium sulfate with acid because they are less soluble than casings and liners.

#### 4.26.5 Treating for MIC

Bacteria cause two major operating problems:

**Biofilms** – bacterial growths that can reduce flow rates and cause plugging.

**Localized corrosion** – due to environment changes, usually under biofilms and deposits, see [Figure 21](#).

The most common forms of bacteria found in natural waters used in oil and gas production/refining facilities are slime forming, and most are

aerobic (often called general aerobic bacteria, GAB): *Pseudomonas*, *Flavobacterium*, *Alcaligenes*, *Bacillus*, and *Aerobacter-Sphaerotilus-Gallionella*. The bacteria responsible for many corrosion problems are the anaerobic sulfate reducing bacteria (SRB): *Desulfovibrio*, *Desulphotomaculum*, and *Desulfobacter*. Some SRB can be found in aquifers having been present for millennia. Other bacteria are oxidizing bacteria and convert sulfide to sulfur/sulfate or oxidize ferrous to ferric and are commonly found in waste water systems and are responsible for degradation of concrete, for example, *Thiobacillus* and *Beggiatoa*. Further details of microbial issues can be found in Stott<sup>13</sup>.

##### 4.26.5.1 Bacteria Monitoring Techniques/Serial Dilution

Samples acquired to estimate populations of free floating bacteria (planktonic) found in fluids, and bacteria attached to surfaces (sessile) are analyzed using similar techniques that comprise a *serial dilution step* followed by an *incubation step* with the concentration of bacteria estimated from changes observed in the sample bottles<sup>9</sup>. More specifically, the technique estimates bacteria concentration (bacteria/ml) by taking a 1 ml sample of the source water and injecting it into 9 ml of a sterile broth media in small, capped bottles. The solution in the bottle is mixed well and 1 ml is extracted using another syringe and the extracted fluid is injected into a second bottle and

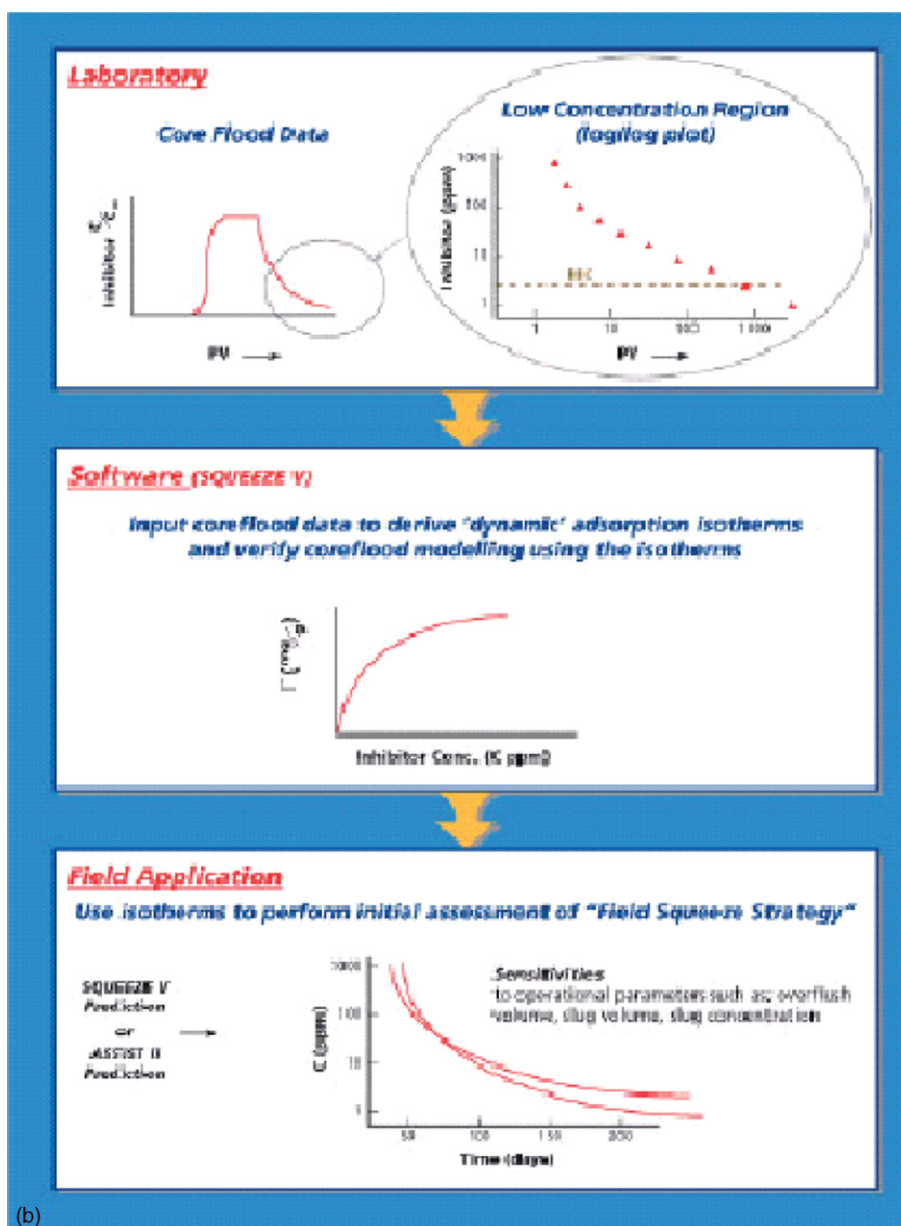

Figure 20

**Figure 20** Continued. Illustration of squeeze application into reservoir.

the same procedure is followed until all six bottles are inoculated. The media contains nutrients and a carbon source with either saline or fresh water. For GAB, the carbon source is dextrose. For SRB, the carbon source is lactic acid together with an iron salt or an iron nail. At the end of the incubation period, the SRB population density in the original sample is determined to the nearest order of magnitude by the number of vials in each dilution series that turn black due to bacterial sulfide production. Tests in which five bottles turned black suggest that the water

sample contains a bacteria count of between  $10^4$  and  $10^5$  bacteria/ml, see [Figure 22](#). The SRB bottles are incubated for 28 days. GAB bottles are incubated for 5 days. Current standards prescribe an incubation period for SRB as a minimum of 28 days, but a very good indication of the SRB count can usually be obtained after 10–14 days of incubation. It can be assumed that if the planktonic bacteria count is high, the sessile bacteria count is also high somewhere in the system. However, a low planktonic count does not suggest that the sessile count is low.

**Figure 21** MIC pitting in an iron sulfide film, morphology of micropits within larger pits. Reproduced from Stott, J. D. F. *Microbial Environments*. In *Corrosion*; Elsevier: London, 2009; Vol. 2.

**Figure 22** Serial dilution test for SRB, five dilutions contain bacteria indicating a heavy infestation.

Ideally, the serial dilution part of the test should be carried out within a few hours of obtaining the subject samples (typically done on site), however, that is frequently not possible. The results become less reliable with increasing time from sampling. Total viable bacteria counts are usually much higher than SRB counts, with planktonic counts of up to  $10^5$  per ml are common in many natural waters and industrial systems. Higher population densities than  $10^5$  per ml probably indicate a significant build up of slime somewhere. In biocide-treated systems, total viable bacteria counts should be several orders of magnitude lower than in the untreated water. The incubation period for total viable bacteria counts is only  $\sim 3$  days, considerably shorter than SRB. Therefore, these counts can give a useful early warning of any problem with biocide-treatment efficiency. GAB populations greater than  $10^4$  bacteria/ml are considered significant.

#### 4.26.5.2 Biocide Treatments

Biocide treatments control bacteria numbers (measured by counting the population density), and the first stage of biocide selection is a laboratory evaluation of candidate biocides using a 'time-kill' test. These tests use a series of biocide dilutions combined with injection of known populations of the bacteria. After the completion of laboratory tests for biocides for a given application (which should include economic considerations and chemical compatibility tests), a program of site monitoring is recommended. The site monitoring should ensure that the chemical injection rate is giving the correct concentration of biocide and is changed when water throughput rate is altered. The monitoring should identify any major perturbations of the system which may affect biocide efficiency. Such perturbations include changes in contact time, flow rates, temperature, pH, use of a new chemical (e.g., corrosion inhibitor, scale inhibitor, or oxygen scavenger), or shutdown periods.

#### 4.26.5.3 Biocide Application

The purpose of biocide treatment is not to kill all bacteria in the system but to control bacteria and economically minimize their effects on corrosion and water quality. Biocide performance is based on success in controlling sessile bacteria, although initially planktonic counting is employed to screen several biocides. Then the biocides that successfully pass this test are tested further for their impact on sessile bacteria (N.B. to acquire sessile samples, growths are carefully scraped or sonically removed. The bacteria population is related to the surface area of the coupon studs with results being reported as bacteria per square centimeter.)

Typical biocide packages are based on:

- Primary amines – cocoamine acetate,
- Diamines – cocodiamine acetate,
- Quaternary amine salts – dialkyl-benzyl ammonium chloride,
- Aldehydes – formaldehyde, glutaraldehyde, acrolin,
- Chlorinated phenols, and
- Oxidizing agents – chlorine, bromine (hypochlorite–hypobromite mixture) usually produced by electrolysis of seawater or brine.

Chlorine dosage has the disadvantage that the water may contain reducing agents with a chlorine demand, where chlorine is consumed by reaction with organic matter and pipework, whilst ammonia

will form chloramines. The chlorine demand must be accounted for and the system is overdosed to a free chlorine 'residual' of typically between 0.2 and 0.5 ppm. Chlorination is not suitable for systems with a high chlorine demand or extensive (several km) exposed carbon steel pipework as the high dosage levels required at the inlet can lead to enhanced corrosion risks, possible stress corrosion cracking of austenitic steel.

There are essentially two classes of biocide treatment, viz. continuous, low level dosing with oxidizing agents and 'shock' treatment using organic biocides. These are often employed together for seawater injection systems where an initial dose of chlorine kills some bacteria and seed macrofouling. The water is then deaerated, removing chlorine and dissolved oxygen and then a batch dose of biocide is periodically sent down the line. Biocide batch treating of water systems controls bacteria with a higher biocide concentration and a shorter contact time. A typical offshore seawater injection system for example, would have continuous use of electrolyzed sea water to control macroorganisms (seed shell fish, etc.) and partially control bacteria followed by batch treatment with glutaraldehyde (e.g.,  $1500 \text{ mg l}^{-1}$  twice weekly) for 1 h, and subsequently, to prevent the development of a dominant bacteria strain with a quaternary ammonium-based bactericide (e.g.,  $500 \text{ mg l}^{-1}$  for 1 h).

Developing a biocide treatment strategy to maintain control of microbial populations is an iterative process. If insufficient biocide is dosed, a greater proportion of the microbial population will recover between dosing than being killed during dosing and the population trend will increase with time. Increasing the dosing regime may then lead to a situation where kill is exactly matched by recovery. Further improvements can lead to an overall reduction in population where kill exceeds the recovery rate. This will lead to a reduction of corrosion in the fluids which is the aim of the biocide treatment strategy.

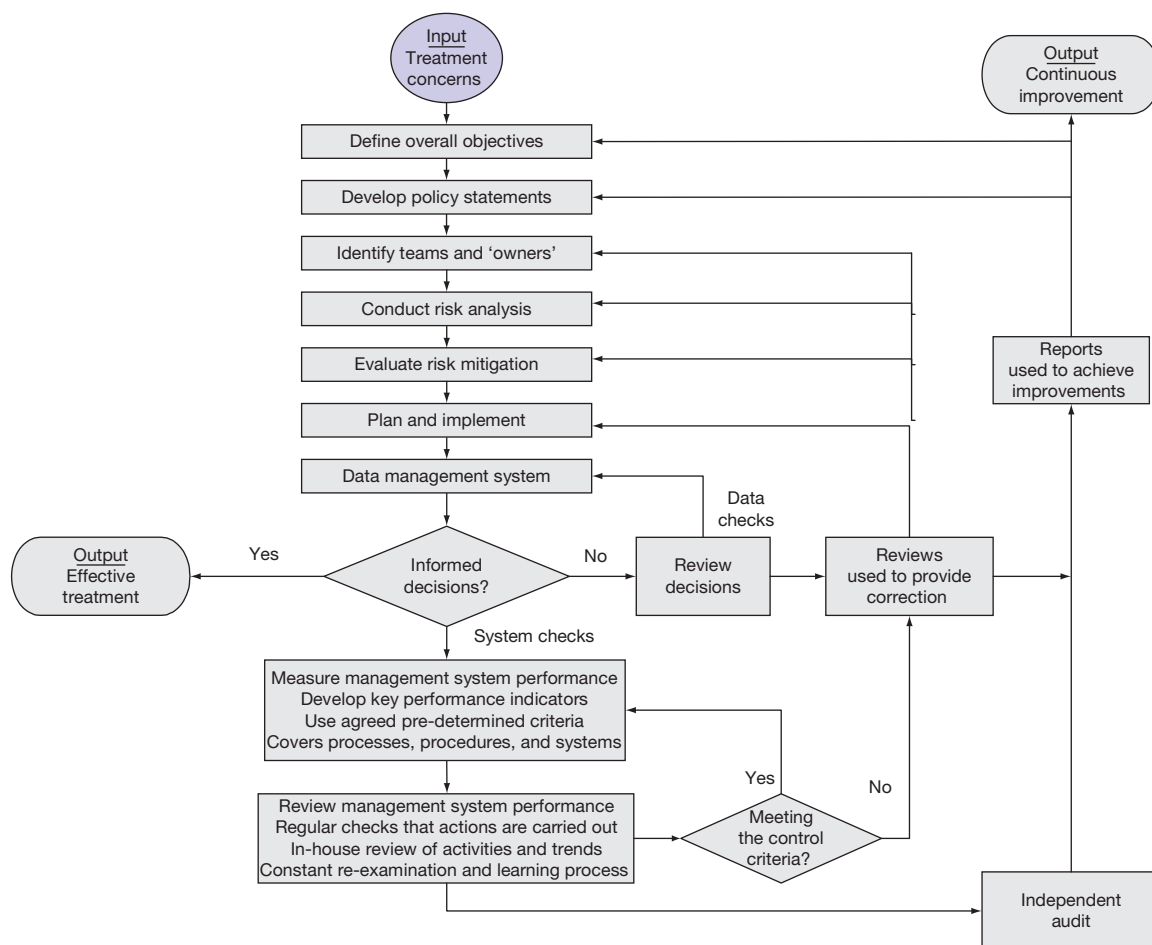

An alternative method to chemical biocide treatment is ultraviolet sterilization, with the disadvantage that it carries no residual protection into systems and does not sterilize sessile bacteria on the metal surfaces. Treatment is only effective against planktonic (free floating) microorganisms in completely optically clear water. Any entrained particles will shield the SRB from the action of the UV radiation. Also, any scale formation or solids deposition on the optical window (even a very thin film) will severely limit the effectiveness of the treatment.

#### 4.26.6 Management of Treating Programs

The use of chemical treating is a strategic decision made during the design stage in the case of corrosion, usually due to the selection of the use of c-steel or low alloy steel in preference to corrosion resistant alloys but in the case of scaling based on reservoir and injection water chemistries. The implications are that provision must be made for the positioning of injection locations, chemical storage, and chemical monitoring facilities. Details of many of these issues can be found in the oil and gas management chapter.<sup>1</sup> In many cases, the need to introduce chemical treating arises during operations due to adverse processing conditions, increased maintenance for cleaning/descaling, or is the result of corrosion damage of equipment found by routine inspection. This change will need a reassessment of corrosion, integrity, and operational issues as well as the sourcing, installation, commissioning, and operation of all associated activities concerned with the treatment programs.

In general, safety, health, and environmental (SHE) polices plus operational and commercial concerns control the development of chemical treating strategies and treating management.<sup>2</sup> The purpose of the treating programs must be clearly stated together with their likely impact on corrosion, asset integrity, maintenance, and operations. There are obvious costs associated with treating – the initial investment or capital cost, personnel recruitment, training, chemical costs, use of contractors or consultants but also benefits – the ability to operate effectively within highly aggressive environments, to push operating envelopes, and improve overall performance. Effective management requires a transparent framework for these activities with the management process involving a series of logical steps as illustrated by the management process flow sheet shown in [Figure 23](#).

The inputs to the flow chart are the treating issues and their impact on maintenance of asset integrity (SHE) and improvement in performance (business outcomes). There are two outputs from the management process, the tactical, which is effective mitigation of the risks from corrosion, scaling, and microbiological infections (decreased rates of corrosion damage, less plugging of strata and equipment) and a continuous improvement of the management process (less risks from leakages or hazards from corrosion, fouling, fracture, wear, plus increased throughput at lower costs). Although this second outcome is a normal requirement of any quality

**Figure 23** Steps in a risk-based treatment management process.

system and the management of SHE issues, it has not received widespread acknowledgment in the management of oil and gas assets or treatment management. This is in spite of the fact that asset management, including chemical treating and corrosion management, requires that products are recovered at lowest possible costs commensurate with meeting SHE requirements.

The flow sheet was developed using a risk-based approach for corrosion management,<sup>2</sup> with the decision-making step based on reputable field data as a key factor in development of strategies. The risks are from both physical and chemical processes (corrosion and scaling) and from management processes often referred to as human errors, when catastrophic failures occur. J. Reason<sup>10</sup> considers that key factors in many industrial equipment failures are due to *latent conditions*, which promote the likelihood of active failures by the creation of local factors that then promote errors. Latent conditions are defined here 'as undiagnosed or

unrecognized flaws or defects in data, data management, systems, documents, procedures and guidance or standards that give rise to human errors.' The need to meet design and operational specifications, including no leaks, minimum unscheduled down time, cost effective production means regular reviews and audits including the development of performance indicators based on acceptable criteria. These audits are also a means of identifying latent conditions in the management system. A continuous improvement approach also has benefits in the control of operational issues – day-to-day activities, monitoring, chemical dosing, etc.

The objectives of a treating program must be transferred through from design to operations and should be encompassed in a policy statement from the senior management. The boundaries and ownership of the program must be clearly defined, as a number of individuals, specialists, teams, and vendors are likely to be involved. Hence, responsibility and

**Table 2** Typical activities, responsible personnel, and implications

<i>What</i>	<i>Who</i>	<i>Comments</i>
Corrosion data	Operators/inhibitor supplier	For all monitored locations – last period and yearly trends
Analysis of data	Corrosion engineer	Is corrosion controlled?
Chemical consumption	Inhibitor supplier/ purchasing	Last period and trend
Chemical problems	Production chemist	Compatibility with other chemicals, water quality
Production rates	Operations	Last period, forecasts with emphasis on impact on chemical usage
Equipment on line availability	Operations/maintenance	Specify cause of outing, duration, cost of repairs
Processing information	Operations	Possible interference of inhibition with processing
SHE performance	Facilities/process	Targets, results (e.g., water discharge compliance)
Operators comments	Operations	Nonspecific problems, issues, suggestions for improvement
Targets for next period	All	Include technical, commercial issues

accountability may become less obvious as projects and operations develop. This is illustrated by a list of activities and personnel involved, see [Table 2](#).

#### 4.26.6.1 Inhibition Risks and Mitigation by Monitoring

One approach is to continuously monitor a number of process parameters (e.g., flow rate, water cut, temperature, etc.) and then be ready to alter the corrosion inhibition conditions appropriately. The concern is that there is no direct measure of metal loss. However, such a strategy may be appropriate in low risk systems where regular corrosion inspections can adequately identify wall thickness change. A more proactive and efficient approach, essential with high risk systems, is to identify the corrosion rate increase and its cause, such as an increase in water cut/process parameter change, as quickly as possible and respond to it immediately. Methods that use insert probes/spool pieces, such as the newer electrical resistance techniques and linear polarization resistance measurements (LPRM) are typically employed but sensitive ultrasonic transducers, permanently attached to the equipment have been used, as have iron counts to determine metal loss rates.

A risk assessment is a normal step in any business activity, and operating companies address inhibition risks differently depending on the type and age of equipment, location, types of fluids, constraints, and experience. There is also an increasing emphasis worldwide for organizations to adopt a risk-based approach to facility integrity and corrosion management, including the management of inhibition programs. Inhibition risks are typically associated with:

- maximum expected uninhibited corrosion rate;
- required inhibitor efficiency;

- required inhibitor availability;
- risks of erosion corrosion (flow regime and velocities);
- risks of pitting/under deposit corrosion;
- temperature that may cause loss of inhibitor performance and scaling;
- precorrosion (old or new system);
- available corrosion allowance (CA) and required life; and
- access for repairs and replacements.

The BP approach to assessment of inhibition risks for pipelines is summarized in the tables that list the categories for a typical 20-year design life with a maximum of 8 mm CA and indicates that inhibition is typically employed when the corrosion rate exceeds  $0.5 \text{ mm year}^{-1}$ . CRAs are used where the uninhibited corrosion rate is  $>6 \text{ mm year}^{-1}$ . Note that the evaluation includes inhibitor availability, the percentage time, the injection of corrosion inhibitor occurs, and also the likely monitoring and inspection requirements to ensure adequate management of the system and to maximize integrity, see [Tables 3 and 4](#).

Monitoring is a risk mitigation method that is used to confirm that inhibition, biocide, etc. are actually controlling the hazards (corrosion, fouling) to an agreed and acceptable rate. Monitoring can detect out of compliance, provide operators with sufficient reaction time to implement remedial action, such as repair of injection equipment, change operating procedures, change dose rate, and/or inhibitor/biocide/scale control package. Common corrosion monitoring methods include:

- chemical/biochemical analysis of fluid samples for changes in composition, water cuts, inhibitor residuals, planktonic bacteria;

**Table 3** Example of a corrosion inhibitor risk evaluation

<i>Risk category</i>	<i>Maximum required availability</i>	<i>Maximum expected uninhib. corr. rate (mm year<sup>-1</sup>)</i>	<i>Comment</i>	<i>Proposed category name</i>
1	0%	0.4	Benign fluids, corrosion inhibitor use not anticipated. Predicted metal loss may be accommodated by corrosion allowance	Benign
2	50%	0.7	Corrosion inhibitor probably required, but with expected corrosion rates there will be time to review the need for inhibition based on inspection data	Low
3	90%	3	Corrosion inhibition required for majority of field life, but inhibitor facilities need not be available from day one	Medium
4	95%	6	High reliance on inhibition for operational lifetime. Inhibitor facilities must be available from day one to ensure success	High
5	>95%	>6	Carbon steel and inhibition is unlikely to provide integrity for full field life. Select corrosion resistant materials or plan for repairs and replacements	Unacceptable

**Table 4** Monitoring and inspection requirements for different inhibitor risks

<i>Corrosion inhibition risk</i>	<i>Overall system requirements</i>	<i>Inhibitor injection system</i>	<i>First inspection schedule</i>	<i>Monitoring of subsea lines</i>
Category 1	Does not rely on corrosion inhibition	No requirement	Inspection determined by previous operation of similar systems	Process monitoring of fluids
Category 2	Inhibition not used in early life but is available when conditions change, i.e., increased water cuts	Commissioning without shutdown	As category 1	Standard inspection techniques at accessible points
Category 3	Inhibition not available due to logistics problems but must be operated as soon as possible	Commissioned as soon as practical and incorporate level device and flow monitor into injection system	Early inspection as determined by anticipated corrosion rates	As category one plus weight loss coupons, ER/LPR probes and occasional intelligent pig runs
Category 4	Corrosion control working on day one. Inhibitor and dose rate preselected	As category 3	As category 3	As category two plus FSM or UT mats system. Continual logging for all monitoring devices
Category 5	Assumes technical, SHE, and financial factors answered satisfactorily requirements as category 4	As category 3	As category 3	As category three plus increased inspection frequency

- ion counts (regular chemical analysis to provide trends);
- corrosion coupons (weight loss and detection of pitting, scales, bio-films);
- insert probes/spool pieces (electrical resistance/modern versions electrochemical – linear polarization resistance/electrochemical impedance/electrochemical noise/galvanic coupling);

- hydrogen probes (electrochemical, beta foils);
- FSM (field signature method) for metal loss/erosion pitting trends;
- ultrasonic strips (UT Mats) for metal loss trends; and
- erosion/sand probes.

Down-hole inspections of tubulars use wireline operations, including calliper surveys and ultrasonic examinations, complemented by visual and wall thickness UT measurements during work-overs. The inspection data, as with process plant examinations (RBI) should be correlated with the on-line corrosion monitoring. The same is true of in-line inspections where the condition of larger diameter pipelines is typically obtained by 'intelligent' pigging, usually magnetic flux measurements. Pipe geometry and vibration monitoring using a 'semi intelligent pig' (SAAM), which operates on the principles of measuring, recording, and detecting any changes in vibration level as the pig travels along the pipeline has also been used to correlate operations with field effects.<sup>11</sup> In addition, the differential pressure levels are detected and recorded along with axial acceleration and temperatures. This type of study demonstrates the importance of correlation of field data in the management process.

Further details on monitoring, including chemical analysis can be found in the Chapter on Oil and Gas Management.<sup>1</sup> The actual methods employed in any specific application will depend on the type of corrosion and the inhibition risk involved.

Tactical planning of the treating programs requires formulation of plans, specifications, assessment of chemicals, likely dose rates, and costs. Performance indicators will have to be developed for all activities, see EFC 39<sup>7</sup> for details.

#### 4.26.6.2 Monitoring and Data Management

Water cut is an important operational parameter that must be monitored; the inhibitor dose rate and partitioning properties must be balanced to achieve optimal inhibitor concentration in the field. These are examples of field data that are continuously being collected and analyzed. Other parameters include the persistency of batch inhibitors that needs to be verified in the field to ensure the viability of the batch treatment. Corrosion monitoring is NOT a replacement for condition monitoring (e.g., use of inspection, intelligent pigs for pipelines, downhole wireline surveys), but an adequately monitored and well-managed chemical

treatment program can provide cost benefits by optimizing the inspection frequency. Process interruptions, such as shutdowns, acid returns, and sand deposits due to loss of gravel packs require their own special set of precautions to prevent continuing corrosion damage in downstream operations.

Data collection is an integral part of any system that forms part of a chemical treating program. Data must also be properly stored to allow easy access for retrieval and analysis. Data are only useful when they are converted into information that can be employed to manage the corrosion. Monitoring for corrosion is only one aspect of managing the total inhibition system. For example, certain types of corrosion monitoring (e.g., weight loss coupons) only reveal an adverse change in the process after it has happened, often a significant time afterwards. These warnings are retrospective and reactive as metal loss has already occurred. Online data used to control chemical treatments require monitoring from chemical analysis, probes/spool pieces plus retrieval of appropriate process data, such as flow rates, temperatures, and fluid compositions from Supervisory Control and Data Acquisition (SCADA) systems. Conversion of data into information requires correlation of various datasets, analysis of trends, and extraction of information related to performance and cost benefits. An IT benchmark product such as *Amulet* has been employed for the management of corrosion data from various offshore and onshore production facilities/refining/oil field treating chemicals as illustrated in the figures. Not only should actual dose quantities of chemical be listed but these should be translated into dosage (ppm) by correlating with actual production rates. In many instances, an audit will show that the quantities of chemical ordered, delivered, in store or received by the field do not correlate with the specified dose.

Inhibition data such as corrosion rates should be correlated with other processing parameters, such as production rates and water cuts, to provide economic information for management. For example, chemical spend based on chemical performance and not dosage or usage targets, see [Figure 24](#). Essentially this converts technical data to money to provide performance measures and criteria, enables compliance to be measured, and benchmarks similar assets. Other parameters could include cost per Ml water processed, cost per MW power, cost per barrel of seawater injected. A typical case is a \$1.6 million per year saving achieved on a \$5.6 million chemical spend as a result of online corrosion data management.

**Figure 24** Comparison of chemical costs per day and per barrel of oil produced, courtesy A. N. Rothwell. Reproduced from Smith, C.; Murphy, B.; Flockhart, S. In *Corrosion'07*; NACE International: Houston, 2007; Paper No 330.

Management of treating programs relies on good decision making that requires information on field performance. This can only be obtained from data analysis that in turn means input of adequate field data. Without adequate data, there is no information and no effective chemical management control.

Further information on various aspects of the review and audit processes can be found in 'Guidance for corrosion management in oil and gas production and processing'<sup>12</sup> that also indicates normative requirements for the UK industry. The strategic decision to use chemical treating of a c-steel system has implications for other materials, such as some corrosion resistant alloys and Ti/Ti alloys. Also, the use of an alliance strategy with a chosen vendor has benefits in terms of a focused program with shared cost savings

but ownership of equipment and field data, etc. has to be agreed prior to contract award.

It is also important to establish technical authority for chemical treating during design, commissioning, and operations and also to ensure that all relevant information is transferred from design to operations. Roles and responsibilities of all personnel have to be clearly defined, especially in large assets where chemical treating involves many disciplines, specialists and operational/maintenance staff, operators, technicians, and managers. System failures usually involve issues associated with data, handling, interpretation, issuing of reports and/or latent conditions within the management system, decision-making or audits for continuous improvement.

### Glossary

**Attemperation** The process for reducing and controlling the temperature of superheated steam.

**Cation conductivity** The measurement of the electrical conductivity of a water sample after it has been passed through a strong acid cation resin that is in the hydrogen form.

**Decarbonator** A degasifier used to remove carbon dioxide.

**Desuperheat** Removing superheat from steam typically by injecting high-purity water or steam condensate.

**Duct burner** A means of auxiliary firing in many combined cycle plant heat recovery steam generators (HRSG's).

**Feedwater heater** A heat exchanger used to raise the feedwater temperature. Low pressure

feedwater heaters are typically located ahead of the deaerator; high pressure feedwater heaters are typically located after the deaerator.

**Mud drum** The lower drum in a boiler circuit that acts as a point of recirculation and collects solids for removal by bottom blowdown.

**Mud drum attemperator** A steam to water heat exchanger located in the mud drum used to control steam temperature.

**Specific conductivity** The measure of the ability of water to conduct an electric current. Often related to the dissolved solids content of the water.

**Steam blanketing** A condition in a boiler tube where the steam water mixture stratifies into separate layers. This is more likely to occur in an inclined tube.

**Sweetwater condenser** A heat exchanger that cools a portion of generated steam so that the resultant condensate can be used for attenuation of the superheated steam.

### 4.28.1 Introduction

Water is abundant on our planet. However, very little is suitable for human consumption (potable) without pretreatment. It is very rare that even potable quality water is suitable for makeup water to a boiler system without additional pretreatment.

There are many technical organizations around the world that publish guidelines on recommended feedwater and boiler water specifications. There are the European Standard<sup>1</sup> and the Vereinigung Grosskraftwerk Betreiber (VGB)<sup>2</sup> in Europe, the American Society of Mechanical Engineers (ASME)<sup>3</sup> and Electric Power Research Institute (EPRI)<sup>4</sup> in the United States, and the JIS<sup>5</sup> in Asia. These guidelines are generally developed by a consensus of committee members that can include equipment manufacturers, industrial equipment operators, water treatment companies, and experienced consultants. Some of these guidelines focus more on a particular segment of the industry than another. For example, the EPRI guidelines focus on boiler systems in the electric utility industry, whereas ASME focuses on boiler systems in industrial

applications. Others may try to cover the entire scope of boiler applications. These guidelines are, for the most part, very general, and only in rare cases do these guidelines specify a treatment chemistry or treatment chemical to use. This is because the actual treatment chemistry used is a function of the makeup water quality available, the desired steam purity to be produced, and economic considerations. For instance, the ASME guidelines relate steam purity to the appropriate boiler water limits but do not specify feedwater purity in terms of total dissolved solid content. This is an economic decision left to the individual boiler system operator to decide how much is invested in the pretreatment system to purify the water as opposed to higher blow-down rates to maintain the boiler water dissolved solid limits. The EPRI guidelines are an example of such an exception from these more general types of guidelines, in that they are intended for a very specific audience of a narrowly defined type of boiler system – in this case, the electric utility industry.

Finally, since these guideline committees are continually updating their guidelines based on the most current information available and the latest operating experience, they will only be referenced in the chapter. For actual guidelines, the most current relevant issue of the chosen guideline should be obtained for use in a particular boiler system.

This chapter addresses the subject of makeup water, feedwater, boiler water, and steam and condensate treatment in steam boiler systems. Feedwater by definition is the combination of returned condensate and fresh makeup water (**Figure 1**). This combination can

**Figure 1** Schematic of typical boiler flows.

range from 0% to 100% in industrial steam-generating systems, in which the steam-generating system is generally part of an industrial or manufacturing plant. **Figure 2** is a typical field-erected water tube industrial boiler. Notably different are steam-generating systems in the electric utility industry, which are dedicated only to the production of electric power and have condensate return rates consistently greater than 95% of the feedwater by design. **Figure 3** is a typical drum-type utility boiler.

#### 4.28.2 Make up Water Treatment

The type of pretreatment will dictate the necessary further chemical treatment that the water will require prior to use in the particular steam-generating system. The possible types of pretreatment are

- clarification,
- cold lime softening,
- hot lime softening,
- zeolite (ion exchange) softening,
- demineralization,
- reverse osmosis (RO).

Clarification is used to reduce the suspended solids of the water; cold lime, hot lime, and zeolite softening are used to reduce only the hardness, that is, the calcium and magnesium content of the water; reverse osmosis (RO) and demineralization are used for a more effective reduction of the total dissolved solids content of the water.

When precipitating processes for hardness removal such as cold or hot lime softening are used as pretreatment, the effluent water pH is inherently high, in excess of a pH of 10.0. pH control is a very important aspect of water treatment to protect the materials of construction of these systems. A secondary benefit of these precipitation processes is the partial reduction of the water's silica content. When these precipitating processes are used to reduce water hardness, it is important to remember to measure the total hardness of the effluent water. This involves an acid digestion step, as opposed to the normal soluble hardness tests, since there can be suspended solids of hardness in the effluent from these systems that the soluble hardness test would not detect and must be accounted for in the chemical treatments applied.

**Figure 2** Field erected water tube industrial boiler.

**Figure 3** Natural circulation drum type utility boiler.

Softened makeup water is generally acceptable for lower-pressure boiler systems. Higher-pressure systems will require more purified water such as that treated by RO or a demineralization processes. A high percentage of condensate return in the feedwater can also produce high-purity feedwater.

Zeolite softening, an ion exchange process using strong acid cation resin in the sodium form, can also be used to remove the hardness from the water. This process can be applied in conjunction with one of the precipitating softening processes or alone. Ion exchange softening can also include a dealkalizer for the alkalinity reduction of the makeup water. This is

typically done using anion resin in the chloride form, but several configurations are possible.

Conventional ion exchange demineralization of makeup water typically involves a two-bed demineralization system. Most common is a strong base cation resin bed in the hydrogen form, followed by a strong base anion bed in the hydroxide form. There may or may not be a decarbonator in between. There are many configurations of these systems available, which vary from cocurrent to counter current regeneration configurations. They may also include alternative resin types, weak acid resin, or weak base resin with multiple cation and anion units,

depending on the starting water composition, the final desired water purity and local economics. For the highest water purity requirements, a mixed-bed resin unit is applied at the end of the process.

RO, a membrane-based water purification system, can be used to reduce the total dissolved solids content of the water. There are numerous configurations of the RO process available that can be chosen based on the water's composition to be treated, the level of effluent purity required versus the percentage of recovery required and the local economics of chemical cost, power cost, and labor cost. The details of these systems are beyond the scope of this chapter and will not be addressed in this chapter. The reader is directed to numerous literature sources available on these topics for specific information.

RO, a semipermeable membrane process, reduces the dissolved substances in water, but this removal is not complete, and effluent or permeate may not yet be suitable for boiler makeup water. A conventional mixed-bed resin polisher, electrodialysis (ED), or some modification of this process can follow the RO.

ED is a membrane process in which mineral salts and other ions are transported through ion-permeable membranes from one solution into another under the influence of a direct current electrical potential. Electrodeionization (EDI) is a modification of the ED process that combines ED with self-regenerating mixed-bed ion exchange resins installed between the membranes. Electrodialysis reversal (EDR) is another modification of ED in which the electrical field is periodically reversed to provide a self-cleaning process that can run at increased recovery rates.

Though these electrochemical processes are available commercially and are capable of producing high-purity water, they are rarely used in the boiler makeup water treatment application and are more likely to be seen in the microchip manufacturing industry. Conventional mixed-bed resin deionization is much more common in the production of high-purity boiler makeup water.

### 4.28.3 Feedwater Treatment

Corrosion protection in the feedwater system is generally achieved by mechanically and chemically removing dissolved oxygen from the feedwater and buffering the feedwater pH into a range suitable for the system materials of construction. Feedwater must

generally be deaerated for industrial steam boiler applications, but there are special circumstances in which full deaeration is not recommended. These are discussed separately.

#### 4.28.3.1 Dissolved Oxygen Control

Dissolved oxygen removal from the feedwater is typically accomplished in a deaerating heater or deaerator in which steam is used to remove the dissolved oxygen from the feedwater. Each of these pieces of equipment has its own dissolved oxygen removal efficiency. In some very low-pressure applications, there may only be a feedwater tank in which makeup water and condensate are mixed, which may or may not be actively steam sparged or otherwise heated to try to remove the dissolved oxygen.

The goal of the mechanical deaeration process is to reduce the dissolved oxygen content of the feedwater to less than 7 ppb for a system using a true deaerator. Dissolved oxygen in the feedwater can cause pitting corrosion damage of the feedwater system components. More complex feedwater systems can include both low- and high-pressure feedwater heaters in addition to an economizer.

Additionally, vacuum degasifiers or deaerating condensers can be used for dissolved oxygen removal. Recently, a semipermeable membrane process<sup>6</sup> has also been developed to reduce the dissolved oxygen content of water. These membrane systems have been used in laboratory environments for more than 25 years but have only recently become commercially feasible for industrial applications. This membrane process can use a combination of vacuum and stripping gas arrangements to deaerate the water. The membrane modules can be arranged in series to produce ppb level oxygen concentrations in the final water. These membranes, dependant on the pH of the water, can also remove carbon dioxide. RO pretreatment is recommended ahead of the gas membrane to prevent fouling. A conventional deaerator also provides only limited removal of carbon dioxide, based on the pH of the water.

After any of these mechanical/thermal deaeration processes, a chemical oxygen scavenger can be applied to further reduce the dissolved oxygen content of the feedwater (Table 1).

Sodium sulfite is the most common chemical oxygen scavenger used in low-pressure boiler systems. It is also available in a catalyzed form, which increases the speed of reaction with the dissolved oxygen. This can be important when the mechanical

**Table 1** Oxygen scavengers used in steam-generating systems

Scavenger	Primary reaction	Comments
Hydrazine	$\text{N}_2\text{H}_4 + \text{O}_2 \rightarrow 2\text{N}_2 + 2\text{H}_2\text{O}$	Toxicity and handling issues
Hydrazine decomposition	$3\text{N}_2\text{H}_4 \rightarrow 4\text{NH}_3 + \text{N}_2$	At temp. $>200^\circ\text{C}$
Sodium Sulfite	$2\text{Na}_2\text{SO}_3 + \text{O}_2 \rightarrow 2\text{Na}_2\text{SO}_4$	Also $\text{NaHSO}_3$ , $\text{Na}_2\text{S}_2\text{O}_5$ , $\text{NH}_4\text{HSO}_3$
Carbohydrazide	$(\text{H}_2\text{N-NH})_2\text{CO} + 2\text{O}_2 \rightarrow 2\text{N}_2 + 3\text{H}_2\text{O} + \text{CO}_2$	Forms hydrazine at temp. $>150^\circ\text{C}$ , $\text{NH}_3$ , $\text{N}_2$ , and $\text{H}_2$ on decomposition
<i>N,N</i> -Diethylhydroxylamine	$4(\text{CH}_3\text{CH}_2)_2\text{NOH} + 9\text{O}_2 \rightarrow 8\text{CH}_3\text{COO}^- + 9\text{H}^+ + 2\text{N}_2 + 6\text{H}_2\text{O}$	Frequently fed with hydroquinone, acetic acid, $\text{CO}_2$ , acetaldehyde, $\text{NH}_3$ at temperatures above $275^\circ\text{C}$
Hydroquinone	$\text{C}_6\text{H}_4(\text{OH})_2 + 1/2\text{O}_2 \rightarrow \text{C}_6\text{H}_4\text{O}_2 + \text{H}_2\text{O}$	Acetates, $\text{CO}_2$ decomposition products, toxicity issues
Erythorbate	$\text{C}_6\text{H}_4\text{O}_6 + 1/2\text{O}_2 \rightarrow \text{C}_6\text{H}_5\text{O}_8 + \text{H}_2\text{O}$	$\text{CO}_2$ , lactic acid, decomposition products
Methyl ethyl ketoxime	$2\text{CH}_3(\text{C}_2\text{H}_5)\text{CNOH} + \text{O}_2 \rightarrow \text{N}_2\text{O} + 2\text{CH}_3(\text{C}_2\text{H}_5)\text{CO} + \text{H}_2\text{O}$	Frequently fed with hydroquinone, $\text{NH}_3$ , $\text{CO}_2$ , ketones, aldehydes on decomposition

deaeration process does not provide sufficient residence time. Sodium sulfite is a nonvolatile inorganic compound that does contribute dissolved solids to the feedwater and the boiler water. This dissolved solids contribution prevents its use in feedwater that is to be used as attemperator spray or desuperheat spray for steam temperature control, as these solids would become impurities in the steam.

The control of sodium sulfite is generally based on maintaining a sulfite residual concentration in the boiler water. This can be a problem in a system where the feedwater system deaeration process and chemical injection point do not provide sufficient residence time and temperature for the chemical oxygen scavenging reaction to be completed prior to the feedwater entering the steam drum of the boiler. Oxygen scavengers and dissolved oxygen can coexist in the feedwater, in such a situation, pitting corrosion can occur. Because of the dissolved oxygen's high volatility, the oxygen preferentially goes into the steam phase when the feedwater enters the boiler steam drum, leaving the unreacted sulfite residual in the boiler water.

Another point of oxygen ingress into the system not to be overlooked is a leak path through the boiler feed pump seals. It is wise not only to monitor the temperature and pressure operating conditions of the deaerating device for proper operation but also to periodically measure the feedwater dissolved oxygen content directly at the boiler or economizer inlet.

Sodium sulfite can also produce some acidic gaseous decomposition products, such as sulfur dioxide, that will be carried out of the boiler in the steam. This can be significant at boiler operating pressures above 4.1 MPa g (600 psi g). These decomposition products can cause low steam condensate pH.

Hydrazine is another available oxygen scavenger that has been used primarily in higher-pressure boiler applications. It is a volatile compound that can be used in feedwater that is used for steam temperature control by attemperation or desuperheating. However due to its status as a suspect carcinogen, its use in industry has declined. When it is used, a closed feed system is typically required.

Given these health concerns, alternatives to hydrazine have been developed. The most common of these are carbohydrazide, erythorbate, diethylhydroxylamine, hydroquinone, and methylethyl ketoxime. Many of these oxygen scavengers also function as passivating corrosion inhibitors. Each is an organic compound that has its own temperature limitations. Decomposition products can vary from only carbon dioxide to several organic acids and other organic compounds. Some decomposition products are more undesirable than others, and the amount of these decomposition products can be application-specific, depending on system temperatures and metallurgy. Each application should be evaluated based on the benefit provided versus the potential undesirable effects of the decomposition products. As a note, commercially available erythorbate can be either in

the acid form or in the sodium salt form. The sodium salt form is nonvolatile, which restricts its use if the feedwater is used as spray attenuation or in desuperheating.

#### 4.28.3.2 pH Control

Feedwater pH adjustments to slightly alkaline conditions are used to minimize corrosion of the feedwater system piping and components, and the resultant corrosion product transport to the boiler. Caustic, neutralizing amines or ammonia are commonly used for this task. Obviously, caustic cannot be used where the feedwater is used as spray attenuation for steam temperature control. The more common amines in use are morpholine, cyclohexylamine, monoethanolamine, diethanolamine, and methoxypropylamine.

#### 4.28.3.3 All Volatile Treatment (Reducing) (AVT(R))

The feedwater target pH range is a function of the feedwater system metallurgy. In the past, a target pH range of 8.8–9.2 had been specified for feedwater systems containing mixed metallurgy – typically heat exchanger components constructed of copper alloys. Recent work<sup>7–9</sup> has shown that reducing conditions in the feedwater system, an oxidation–reduction potential (ORP) of –300 to –350 mV at 25 °C (77 °F), measured between a Pt electrode and a Ag/AgCl (saturated KCl) reference electrode, at the deaerator inlet, are necessary to minimize copper corrosion and corrosion product transport in these mixed-metal feedwater systems. This work showed that the feedwater pH is a secondary control parameter, which should be restricted to a pH range of 9.0–9.3. EPRI has used the terminology AVT(R), all volatile treatment (reducing) to describe this treatment chemistry. In practice, many systems are not able to reach these low levels of ORP, but copper corrosion and copper corrosion product transport have been successfully reduced in some systems with feedwater ORP levels of even –200 to –100 mV at 25 °C (77 °F), measured between a Pt electrode and a Ag/AgCl (saturated KCl) reference electrode.

This treatment chemistry is expected to reduce corrosion product transport to the boiler system for all operating pressure boiler systems, but is most critical for the very high-pressure boiler systems used by the electric utility industry, where at their operating pressures (>16.4 MPa g (>2400 psi g)),

copper has volatility properties into the high-pressure saturated steam and has caused deposition problems in the high-pressure steam turbine. This deposition in the steam turbine can limit steam throughput and megawatt output. Although the consequences of high copper corrosion product transport to most industrial boiler systems are not as dire as in the very high pressure electric utility boiler systems, only more frequent chemical cleaning of the boilers may be required; this new information on copper corrosion and strategies to minimize it should also be applied to industrial mixed metallurgy feedwater systems.

Theoretically these reducing conditions should be maintained by lay up practices even when the system is out of service, to prevent the reversion of the more protective, more reduced form of copper oxide, cuprous oxide,  $\text{Cu}_2\text{O}$ , formed in service, to the more oxidized and less protective form of copper oxide, cupric oxide  $\text{CuO}$ . Based on the actual circumstances of the out-of-service period, it may not be practical to maintain a reducing environment.

This work<sup>7,8</sup> also showed that the desired reducing environment could not be achieved by the addition of excessive amounts of a chemical reducing agent such as an oxygen scavenger to compensate for a mechanical problem in the system such as a malfunctioning DA or high levels of air in leakage into a condenser or hotwell.

For an all-steel metallurgy feedwater system, the feedwater pH target range is somewhat more alkaline pH = 9.3–9.6. For most industrial boiler feedwater systems, definitely those with softened water make up even those with demineralized make up water or high percentages of condensate return, it is still advisable to fully deaerate the feedwater and treat the system with a chemical oxygen scavenger to prevent dissolved oxygen pitting corrosion damage to the feedwater system components, as previously discussed.

#### 4.28.3.4 Flow Accelerated Corrosion

In boiler systems in dedicated electric utility service, where the typical percentage of condensate return in the feedwater is over 95%, the feedwater most likely will be pure enough to make the system susceptible to flow accelerated corrosion (FAC) damage.<sup>10–13</sup> FAC is a corrosion mechanism that can cause corrosion damage and failures in feedwater systems including economizers, feedwater heaters, and piping. EPRI has compiled a significant amount of information on this topic as it relates to boiler systems in dedicated electric utility service.<sup>14</sup>

FAC is a very localized damage mechanism that affects predominantly areas of flow turbulence in the feedwater system. It is a primarily hydrodynamic phenomenon that prevents the formation of the normal protective oxide (magnetite) coating to form on carbon steel and prevent any further metal loss. FAC is a process whereby the normally protective oxide surface dissolves into a moving fluid. The most susceptible systems are typically all-steel, and employ very high-purity feedwater, due to the purity prerequisite of the steam purity required by the steam turbine in these systems. A significant amount of research has been done on this topic in power plants and is very well documented.<sup>14</sup> FAC is possible at a water temperature range of 100–250 °C (212–482 °F), but there seems to be a maximum susceptibility at about 150 °C  $\pm$  28 °C (300 °F  $\pm$  50 °F). Even though FAC is primarily a hydrodynamic phenomenon, those mechanical parameters that control velocity and turbulence are fixed and not easily changed in an existing system. The research work has identified two water chemistry parameters that influence FAC behavior that can be optimized – feedwater pH and ORP.

#### **4.28.3.5 All Volatile Treatment (Oxidizing) (AVT(O))**

EPRI has developed a feedwater treatment philosophy for boilers in the electric utility service industry that has been termed AVT(O),<sup>4</sup> all volatile treatment (oxidizing), to minimize the potential for FAC in these systems. With AVT(O) treatment, no chemical oxygen scavenger is fed and a nominal amount of dissolved oxygen, (typically  $<10 \mu\text{g l}^{-1}$ ,  $<10 \text{ ppb}$ ) is considered acceptable. This is expected to result in an ORP of  $-50$  to  $+50 \text{ mV}$ , measured between a Pt electrode, and a Ag/AgCl (saturated KCl) reference electrode. This condition is considered less susceptible to FAC than the completely oxygen deficient-reducing conditions of AVT(R) in this high-purity feedwater. Feedwater cation conductivity required for AVT(O) is less than  $0.2 \text{ mS cm}^{-1}$ .

All the discussion on ORP measurement of feedwater up to this point has been regarding the measurement of the ORP of a sample cooled to room temperature, 25 °C (77 °F). Room temperature ORP measurements have had problems with a lack of sensitivity and response. The capability to measure the feedwater ORP at system temperature has been developed, AT ORP™ (originally known as @T ORP™).<sup>15,16</sup> The potential is measured against an external pressure balanced reference electrode

(Ag/AgCl//0.1 N KCl). This technology is much more responsive to system changes that affect ORP. These at temperature ORP measurements can be made at feedwater temperatures up to 260 °C (500 °F).

Feedwater pH is another chemistry parameter that affects FAC, and for an all-steel feedwater system, typically the more alkaline the better (pH  $> 9.2$  up to about 10.0). Even though the feedwater system may be all-steel, there may be a copper alloy condenser that could limit the feedwater pH adjustment to prevent yellow metal attack of the condenser that can occur when ammonia is the alkalinizing agent or a decomposition product.

This near-neutral ORP control, AVT(O), is quite acceptable for high-purity boiler feedwater systems such as those in the electric utility industry, in which the level and consistency of feedwater purity is high. Industrial boiler feedwater systems employing high-purity feedwater are also potentially susceptible to FAC, but the possible chemistry-related corrective actions are not nearly as clear. In industrial boiler systems, even when make-up water is demineralized, the required level of purity for this treatment –  $<0.2 \text{ mS cm}^{-1}$  – is rarely achieved. Additionally, because of the lower percentage of condensate return and the very significant potential for constant low levels and periodic high levels of contamination, feedwater purity can be very inconsistent. For these industrial systems, the simultaneous presence in the feedwater of dissolved oxygen and any feedwater contamination provides the potential for oxygen pitting damage of the feedwater system, especially heat exchanger components, such as an economizer. From the existing research work, it is unclear how pure feedwater must be in order for dissolved oxygen to act as a corrosion inhibitor rather than cause the pitting damage common in industrial systems. From the experience with AVT(O) and oxygenated treatment (OT), feedwater cation conductivity of  $<0.2$  and  $<0.15 \text{ mS cm}^{-1}$  respectively are conditions in which dissolved oxygen acts as a corrosion inhibitor. But even the OT guidelines recommend ceasing oxygen feed and going to an AVT(O) treatment when cation conductivity exceeds  $0.3 \text{ mS cm}^{-1}$ . There are no further guidelines for acceptable higher levels of cation conductivity in the feedwater for AVT(O). OT is discussed in the next section.

This FAC mitigating philosophy of AVT(O) near-neutral ORP can also be accomplished in industrial systems by feeding a very low level of one of the available organic oxygen scavengers/passivators. In this treatment scheme, the oxygen scavenger/passivator is not fed in the stoichiometric ratio to scavenge the

dissolved oxygen but rather is fed at a rate to passivate the steel and provide the neutral ORP target. The feedwater concentration needed to accomplish this ORP is unique to each of the scavengers (hydroquinone, erythorbate, carbonylhydrazide, diethylhydroxylamine, methylethyl ketoxime). In this treatment, when there is an excursion in the chemistry or dissolved oxygen concentration due to mechanical problems, the scavenger feed is able to compensate. We note that sodium sulfite, although it is an oxygen scavenger, cannot be used for this purpose, as it does not appear to have any passivating properties for steel.

Finally, monitoring feedwater ORP does not supply quantitative information regarding FAC, only qualitative information. It has been found that measuring the soluble iron concentration of the feedwater<sup>17–19</sup> at various points in the system can provide more quantitative information regarding FAC. Given that FAC is a very localized damage mechanism related to flow turbulence, it is important to sample the feedwater before and after a feedwater system component with a large surface area subjected to local flow turbulence for this soluble iron testing. Such a component is typically an economizer or feedwater heater with heat transfer surfaces constructed of carbon steel. Detecting a significant increase in the soluble iron content of the feedwater between the inlet and outlet indicates a potential for FAC in the system. Then optimizing feedwater treatment chemistry parameters (feedwater pH, ORP/oxygen scavenger feed) individually and reviewing their impact on the change in feedwater soluble iron content demonstrates the potential impact that feedwater chemistry changes can have on FAC in the feedwater system.

As soluble iron in the water is relatively unstable, soluble iron determination requires careful sample handling to minimize the potential to oxidize the soluble iron in the sample. Feedwater dissolved oxygen content should be less than 20 ppb, and it has been found that it is best to take the sample directly into the reagent to preserve the iron in the soluble state. There have been a number of different ferroin compounds used to determine iron spectrophotometrically.<sup>17,18</sup> One of the most widely used compounds is 3-(2-pyridyl)-5-6-bis (4-phenylsulfonic acid)-1,2,4-triazine, monosodium salt. The test procedure involves collecting samples directly into an acid-cleaned, iron-free container containing the ferroin reagent. Stainless steel sample lines are required.

Even though this soluble iron testing gives a more quantitative picture of the FAC susceptibility of a system and this information can be used to optimize

feedwater chemical treatment, it cannot identify a specific feedwater system component that could be experiencing a particularly high local rate of FAC damage. For this reason, it is still recommended that such a system have periodic nondestructive testing performed on susceptible components (tees, elbows, piping, downstream of valves, flow orifices, etc.) especially those that are in the more prone temperature environment, with water at  $150^{\circ}\text{C} \pm 28^{\circ}\text{C}$  ( $300^{\circ}\text{F} \pm 50^{\circ}\text{F}$ ).

It has been found that in most cases, feedwater chemistry optimization has been able to reduce FAC rates in high-purity industrial boiler feedwater systems prone to FAC but not eliminate them, even in some cases where the treatment has been converted to AVT(O). But as the research work<sup>10</sup> on FAC has shown, commercially available low-chrome alloys (>1% chromium content) are much less susceptible to FAC than carbon steel. Replacing a carbon steel component found to be thinning due to FAC with one of these low-chrome alloy alternatives has eliminated future FAC damage in all but the most extreme situations.

#### 4.28.3.6 Oxygenated Treatment

OT<sup>20–25</sup> is a feedwater treatment developed for once-through boilers in the electric utility industry in Germany in the 1960s. Prior to OT, these boilers were treated with all volatile treatment (AVT) using ammonia and hydrazine. With this conventional AVT treatment, these boilers required frequent chemical cleaning to prevent the accumulation of corrosion products from the feedwater system (primarily iron oxide) in the boiler. These deposits caused pressure drop increases in the boiler's flow circuitry and insulating deposits on high heat transfer areas of the boiler, which could lead to overheating damage.

A once-through boiler is an inherently high-purity feedwater system, since the feedwater purity must meet the steam turbines steam purity requirement. Most of the once-through boilers in Germany operate at subcritical pressures, whereas most of the once-through boilers in the United States operate at supercritical pressures. Most of these systems have all-steel feedwater systems and full-flow condensate polishing.

In these systems, it was found that low levels of dissolved oxygen added to this high-purity feedwater acted as a corrosion inhibitor, producing a more protective oxide on the steel than conventional AVT. This reduced corrosion product transport to and accumulation in these boilers. Most of the once-through boilers in operation worldwide today have now been converted to OT. Some boilers on OT treatment in

Germany have never required chemical cleaning. Once-through boilers in the United States that have converted to OT have significantly extended the time required between required chemical cleanings.

Typical control parameters for OT are a feedwater cation conductivity of less than  $0.15 \text{ mS cm}^{-1}$ ; feedwater pH and dissolved oxygen can be controlled by either what is termed the neutral method, which involves maintaining the pH in the range of pH 7–8 and a dissolved oxygen content of  $50\text{--}250 \mu\text{g l}^{-1}$  (50–250 ppb), or the combined method in which the feedwater pH is 8–9 and the dissolved oxygen content is  $30\text{--}150 \mu\text{g l}^{-1}$  (30–150 ppb). Only ammonia can be used in this treatment as the alkalinizing treatment chemical; dissolved oxygen degrades the more complex amines, increasing the cation conductivity.

OT is only occasionally used on high-pressure drum-type boilers because they rarely have the prerequisite feedwater system metallurgy and the consistent level of feedwater purity required, which typically requires a full flow condensate polishing system. Finally, the required chemical cleaning requirements for drum-type boilers that do meet the metallurgy and feedwater purity requirements are already quite long; therefore, OT does not provide the same economic benefit as it does to once-through boilers. OT for these drum boilers could provide a benefit regarding FAC potential in their feedwater systems, but this benefit is also provided by the AVT(O) feedwater treatment.

## **4.28.4 Boiler Water Treatment**

### **4.28.4.1 Residual Phosphate Treatment**

Boiler water internal treatment options are dependant on the type of makeup water pretreatment, percent condensate return, and boiler operating pressure. For softened makeup water systems, one of the most common internal treatments is residual phosphate treatment, a precipitating treatment for the hardness contaminants in the feedwater.

This treatment chemistry is designed to purposefully precipitate the feedwater hardness contaminants into more desirable, less adherent forms than if they precipitated on their own in the boiler due to their retrograde solubility characteristics. The intent is to precipitate calcium as basic calcium phosphate and magnesium as magnesium hydroxide by maintaining an appropriate boiler water orthophosphate residual and a free hydroxide concentration. The orthophosphate concentration must be measured on a filtered boiler water sample.

A synthetic organic polymer or naturally occurring organic material such as lignins or tannins may be used to help disperse the resultant precipitated suspended solids. The precipitated calcium and magnesium contaminants, though in a more desired form, are still difficult to remove from an operating boiler via the continuous blowdown. This is because they are entrained in the boiler's internal circulation between the downcomer and riser circuitry, which is many times the flow rate of the steam that the boiler actually produces. This circulation continually passes the particulates past the high heat transfer areas of the boiler, where they can form deposits. Suspended solids caught up in the boiler's internal circulation are also not removed very effectively by a boiler's intermittent blowdown system (mud drum blowdown), if the boiler has this capability. Because of the limited effectiveness of the boiler blowdown systems in removing suspended solids, the success of residual phosphate treatment is very much dependent upon minimizing the hardness contaminants in the feedwater and potentially cleaning the boiler, chemically or mechanically, periodically, to control deposit accumulation in the boiler.

Residual phosphate chemistry is controlled by maintaining an orthophosphate residual in the boiler water that is chosen as a function of the boiler's operating pressure, [Table 2](#). Free hydroxide levels in the boiler water are typically maintained at a level of three times the boiler water silica concentration to aid in maintaining silica mineral solubility in the boiler water. In higher-pressure boiler applications ( $>4.1 \text{ MPag}$  ( $>600 \text{ psi g}$ )) where volatile silica transport into the saturated steam is a concern, or anytime the steam being produced is for use in a condensing steam turbine, maximum boiler water silica concentrations are maintained to limit the silica concentration in the saturated steam to the specified limit for the turbine (typically  $10\text{--}20 \mu\text{g l}^{-1}$  (10–20 ppb)) silica in the steam).

### **4.28.4.2 Steam Purity**

Boiler water total dissolved solids are maintained at or below a maximum value to control the overall purity of the saturated steam required. More stringent steam purity limits are required for that steam when it is to be used in a condensing steam turbine application as opposed to a process heating application. With the exception of silica, which has vaporous solubility characteristics in saturated steam, all other nonvolatile species of concern in boiler applications at less than

**Table 2** Typical control limits for residual phosphate treatment

Boiler water component (ppm)	Drum pressure (psi g; MPa g)			
	150 (1.0)	300 (2.1)	600 (4.1)	900 (6.2)
TDS (max) <sup>a</sup>	4000	3500	3000	2000
Phosphate (as PO <sub>4</sub> )	30–60	30–60	20–40	15–20
Hydroxide (as CaCO <sub>3</sub> )	300–400	250–300	150–200	120–150
Sulfite	30–60	30–40	20–30	15–20
Silica (as SiO <sub>2</sub> ) max <sup>b</sup>	100	50	30	10

<sup>a</sup>The limits on TDS will vary with the design of the boiler and with the needs of the system with regard to steam purity.

<sup>b</sup>Example silica values are listed but if silica volatility is a concern, such as condensing steam turbine applications, available pressure dependant and pH dependant control curves on boiler water silica concentration should be used. Silica may be carried at higher levels if there are no condensing turbines in the cycle. In any case, maintain an OH/SiO<sub>2</sub> ratio of at least 3/1 to inhibit silica deposition.

13.7 MPa g (2000 psi g) end up in the steam as a result of mechanical carryover of boiler water droplets that pass through the mechanical separating equipment in the steam drum. Therefore, the steam purity is directly proportional to the boiler water purity.

The restrictions on boiler water total dissolved solid limits to maintain the same steam purity do vary with boiler operating pressure and are more restricted at higher operating pressures because the mechanical steam/water separation process is more efficient when the density difference between the steam and water phases is greater.

Sodium salts and copper oxides, considered non-volatile at lower operating pressures exhibit volatility characteristics above 16.4 MPa g (2400 psi g). This mode of transport into the steam must also be considered and controlled by the appropriate measures to maintain the desired steam purity.

In addition, when attemperation is used for final steam temperature control, the impact of that attemperation water on the final steam purity must also be considered, in the design stage as well as while diagnosing steam purity problems. The potential sources of attemperation water are feedwater (if it is pure enough), condensate and a sweetwater condenser. A sweetwater condenser is typically a shell and tube heat exchanger that condenses saturated steam with incoming feedwater. That condensed saturated steam is then used as attemperation water for steam temperature control. Each of these sources of attemperation water can be potentially contaminated and impact on steam purity. A mud drum attemperator may also be used for steam temperature control. This is typically a heat exchanger located in the mud drum. By design, there is no intended contact between the steam and the boiler water, but in the event of a leak in the exchanger boiler water can contaminate the steam.

#### 4.28.4.3 Chelant Treatments

Realizing the shortcomings of residual phosphate chemistry in the way it handles feedwater hardness contamination (precipitation), alternative treatment chemistries were developed.

The first was the use of chelants to solubilize the hardness contaminants. The most common chelants used were ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA). Both EDTA and NTA form soluble complexes with calcium and magnesium that are stable to relatively high temperatures, up to 6.8 MPa g (1000 psi g). The removal of hardness contaminants from the boiler, now in a soluble form, are no longer limited by the continuous blowdown's limited ability to remove suspended solids from the circulating boiler water. If the species in question is soluble in the feedwater, remains soluble in the boiler water and is nonvolatile, the continuous blowdown removes that species at 100% efficiency.

Theoretically, if the required stoichiometric ratio of chelant to hardness were maintained, there would be no accumulation of hardness-based deposits in the boiler. However in practice, there are variations in the level of hardness contaminants in the feedwater, and some overfeed must be applied continually to account for these variations. This overfeed is typically controlled to result in a small residual chelant concentration in the boiler water above that required for the actual hardness. It was found that this boiler water chelant residual must be controlled very tightly because high levels of the residual can result in corrosion of the boiler base material. This corrosion is most likely to occur in areas of high fluid velocity or turbulence in the boiler. For this reason, chelant residual control limits vary as a function of boiler operating pressure and range from about 1–5 mg l<sup>-1</sup> (1–5 ppm). Chelants have been

applied at boiler pressures over 6.8 MPa g (1000 psi g) early in their history but later were only commonly applied up to about 2.7 MPa g (400 psi g) for EDTA and about 6.2 MPa g (900 psi g) for NTA.

Today, chelants are rarely used for several reasons. NTA is classified as a suspected carcinogen, the potential corrosion problems, and challenges in controlling the required residual level and alternative treatment chemicals have been developed.

#### **4.28.4.4 All Polymer Treatment**

Technically, the ability of the chelant chemistry to maintain the solubility of feedwater hardness contaminants is a much more effective way to control hardness deposit accumulation in boiler systems than residual phosphate treatment. Synthetic organic polymer chemistries have been developed that also have chelating abilities for hardness control. These are based typically on polyacrylate or polymethacrylate polymers. Such synthetic organic polymers can be applied in what is termed an all-polymer treatment, the purpose of which is the same as the chelant chemistry: form a soluble complex with calcium and magnesium and maintain that soluble complex at boiler water conditions to allow for the efficient removal of these contaminants from the boiler in the continuous blowdown as dissolved solids. In addition to the ability of these polymers to maintain soluble hardness contaminants, they are typically anionically charged, whereas suspended solid contaminants such as iron oxide tend to be cationically charged. The polymers also have the ability to disperse particulate contaminants. This dispersion minimizes their ability to agglomerate into larger particles as well as adhere to the heat transfer surfaces of the boiler. But as a suspended solid, there is still the same physical limitation on the ability of the continuous blowdown to remove even these dispersed contaminants from the boiler.

There are many synthetic organic polymers in use in boiler water treatment. It is important to note that not all of these polymers have chelant properties relative to calcium and magnesium, and it is only those that do that can be used as an 'all-polymer' treatment for feedwater hardness contamination. And even those polymers that do have this chelating ability must be of an appropriate molecular weight for the boiler operating pressure and saturation temperature to function as intended. Polymers that do not have the chelant properties with respect to hardness tend to act only as dispersants and therefore do

not have the same effectiveness in handling feedwater hardness contamination.

Even though the polymers used in the 'all-polymer' technology have chelant properties, they are much weaker chelants than EDTA or NTA. As much weaker chelants, the need to control the excess polymer residual relative to the hardness is much less critical. However as with all solubilizing treatments, the potential for corrosion of the boilers base material must be recognized and an appropriate control strategy used.

As there are many synthetic polymer treatments on the market today and most are offered as proprietary treatment chemistries by water treatment companies, hopefully the end user can ask the appropriate questions based on the information provided, such as what the purpose and abilities of their available products are and what the control limits and control strategies are, to decide while choosing between various offerings to best meet his/her needs.

Polymeric dispersants are also used within other treatment philosophies, such as in chelant treatments to disperse iron oxide contaminants and in residual phosphate treatment to disperse the resultant calcium and magnesium precipitated suspended solids. In these cases, however, the concentration of the polymers to hardness is much less than the stoichiometric requirement to solubilize the hardness, and as such they only act as a dispersant and do not compete with the primary intended purposes of the chelant or phosphate chemistry.

In industrial boiler systems, there have been many mixed treatment chemistries that have had mixed success — chelant/polymer, chelant/phosphate, polymer/chelant/phosphate, etc. There are too many to address specifically.

#### **4.28.4.5 Coordinated Phosphate Treatment**

In the past, it was more common to find high-purity feedwater in only high-pressure boiler applications >6.8 MPa g (>1000 psi g). Today the use of high-purity makeup water in low-pressure boilers is much more common.

Coordinated phosphate chemistry<sup>26</sup> was developed as a response to caustic embrittlement failures of boiler drums. In the early days of boiler water treatment, prior to the development of efficient make-up water pretreatment systems, coagulation internal treatments were used. This type of treatment used soda ash ( $\text{Na}_2\text{CO}_3$ ) to precipitate the hardness

salt contaminants into the desired form and then added organic materials (tannins and lignin) to condition this precipitated material (sludge) where hopefully it would settle in the mud drum and be removed from the boiler via the intermittent blowdown (mud drum blowdown) practice.

The use of soda ash introduced high levels of alkalinity, including free hydroxide or caustic alkalinity, into the boiler water, and at that time boiler drums were constructed by riveting rolled sections of steel plate together. These mechanical joints were prone to leaking. When a leak did occur, the leaking boiler water containing free hydroxide would flash to steam, resulting in very high local caustic concentrations at the site of the leak. Carbon steel is susceptible to stress corrosion cracking failure when it is highly stressed and in contact with high concentrations of caustic. The geometry of the riveted construction provided a location of stress concentration, and the flashing boiler water provided the environment that resulted in the potential for stress corrosion cracking or caustic embrittlement failure of the steel. In the early days of boiler water treatment, these embrittlement failures and sometimes resultant boiler explosions were not uncommon, and there were fatalities. Coordinated phosphate chemistry control was developed as a chemical solution to this problem. Coordinated phosphate chemistry balances the boiler water pH and orthophosphate concentration to a maximum Na:PO<sub>4</sub> molar ratio of 3.0:1 to theoretically prevent the formation of free hydroxide in the boiler water. For control, a minimum Na:PO<sub>4</sub> ratio of 2.2:1 is chosen to buffer low pH concerns. It is

important to note that the Na:PO<sub>4</sub> molar ratio used in this treatment as well as the other high-purity phosphate chemistries is not determined by directly measuring both the boiler water sodium and phosphate concentration and calculating the ratio but rather is determined by measuring the boiler water pH and orthophosphate concentrate and then plotting that data on a graph similar to [Figure 4](#).

The reason for this is that in most boiler systems, there are neutral sodium salts present that do not affect the boiler water pH. There can also be contaminants in the makeup water such as organic materials that can decompose to form organic acids in the boiler water, affecting boiler water pH but with no contribution of sodium.

With this in mind it is also important to realize that what affects the boiler water pH and phosphate relationship is that which is added intentionally as the treatment chemicals and that other contaminants may concentrate in the boiler water and affect pH (organic materials in the makeup water or sodium leakage [NaOH] from the make up demineralizer). Sodium salts of various phosphate species and sodium-to-phosphate molar ratios and sodium hydroxide may have to be used to buffer the pH into the desired control range in these situations.

#### 4.28.4.6 Congruent Phosphate Treatment

Caustic problems in boiler systems were not totally alleviated by the adoption of coordinated phosphate chemistry. This was thought to be due to the

**Figure 4** pH vs. PO<sub>4</sub> graph at different Na/PO<sub>4</sub> molar ratios.

solubility characteristics of sodium phosphate salts – a characteristic known as incongruent precipitation. Studies<sup>27</sup> showed that precipitation of phosphate from a high temperature (300 °C, 572 °F) sodium phosphate solution having a Na:PO<sub>4</sub> molar ratio greater than 2.85:1 always results in an increase in the Na:PO<sub>4</sub> ratio of the remaining solution, toward or further into the free caustic region above the 3.0:1 ratio boundary. Conversely, when phosphate is precipitated from a solution having a Na:PO<sub>4</sub> ratio less than 2.85:1, the Na:PO<sub>4</sub> ratio decreases in the remaining solution, further away from the free caustic region. With a solution Na:PO<sub>4</sub> ratio of exactly 2.85, the Na:PO<sub>4</sub> ratio in the precipitated phosphate solids is identical, that is, congruent.

Subsequent studies showed that at higher temperatures, the congruent point could be at a Na:PO<sub>4</sub> ratio as low as 2.6:1. Again, control is based entirely on the relationships of boiler water pH and orthophosphate concentration, endeavoring to keep their plotted coordinates within the appropriate zones on a control diagram (see **Figure 1**).<sup>28</sup> Congruent phosphate<sup>29</sup> then is a refinement of the original coordinated phosphate treatment with new boundaries on the Na/PO<sub>4</sub> molar ratio; a maximum ratio of 2.6:1 and a minimum ratio of 2.3:1. The actual PO<sub>4</sub> concentration control range is typically chosen based on boiler operating pressure and the degree of control capability in the plant and the consistency of feed-water quality (purity). Generally, higher phosphate control ranges (10–20 mg l<sup>-1</sup> (10–20 ppm)) at lower boiler operating pressures and lower phosphate control ranges (5–10 mg l<sup>-1</sup> (5–10 ppm)) at higher boiler operating pressures are employed.

When the chosen PO<sub>4</sub> control range is less than 2 mg l<sup>-1</sup> (2 ppm) in the boiler water, the effect of ammonia or neutralizing amines must be taken into account due to their effect on the boiler water pH measurement at room temperature.

Even though boiler drums are constructed using welded joints today, most industrial boilers operating at less than 6.8 MPa g (1000 psi g) are constructed with mechanical roll expanded joints to connect the tubes between the steam drum and the mud drum. Therefore, there is still the possibility of a local caustic embrittlement failure of the drum if one of these mechanical joints were to leak and the boiler water contained free hydroxide. Congruent phosphate chemistry provides a level of protection for these boilers from this failure mechanism and would be a preferred choice provided the feed-water purity requirements are met and the boiler

is not experiencing phosphate hideout behavior (see the following section) due to the congruent phosphate treatment.

#### **4.28.4.7 Phosphate Continuum Treatment (Formerly Equilibrium Phosphate Treatment)**

Congruent phosphate programs can be difficult to control because of phosphate hideout.<sup>30</sup> Phosphate hideout is the simultaneous decrease in the phosphate concentration of the boiler water and an increase in boiler water pH during a load or heat flux increase. Hideout return is the reverse during a load decrease – phosphate concentration increases and boiler water pH decreases. Equilibrium phosphate control solves this problem and has therefore gained acceptance with electric utility drum boiler operators.

As phosphate hideout occurs, the phosphate concentration in the bulk boiler water is reduced down to very low remaining equilibrium levels. The boiler water phosphate might drop from a normal 5 mg l<sup>-1</sup> (5 ppm) down to 2 mg l<sup>-1</sup> (2 ppm) or even less during hideout. Attempts to maintain the original boiler water phosphate levels by adding phosphate during hideout are usually futile, because ongoing hideout simply continues to remove boiler water phosphate down to the equilibrium level.

In the past, phosphate hideout had been thought to be associated with the retrograde solubility behavior and incongruent precipitation behavior of sodium phosphates, but laboratory research work<sup>31</sup> has shown that phosphate hideout is actually the temperature-dependent reaction of low Na:PO<sub>4</sub> molar ratio compounds in the boiler water with magnetite. These reactions are significant when boiler water Na:PO<sub>4</sub> molar ratios are 2.3–2.6:1, but are essentially nonexistent when the boiler water Na:PO<sub>4</sub> molar ratio is greater than 2.85:1.

During phosphate hideout, phosphate wastage of the boiler metal can result due to the concentration of low Na:PO<sub>4</sub> molar ratio materials in high-heat flux zones. Maracite (NaFePO<sub>4</sub>) and/or Iron Phosphate (FePO<sub>4</sub>) are the residual corrosion products found on boiler tubes damaged by the phosphate wastage mechanism.<sup>32</sup>

Phosphate hideout and phosphate wastage are more likely at higher boiler operating pressures but are also possible in lower-pressure boilers with high local heat fluxes. Phosphate wastage corrosion predominantly occurs in conventional boilers operating at greater than 13.8 MPa g (2000 psi g), although it has been seen in an industrial boiler operating at 6.9 MPa g

(1000 psi g) that was experiencing steam blanketing. It is also common in vertical shell-and-tube steam generators; these are commonly unfired process boilers with flat tube sheets and deep oxide sludge deposits on the tube sheet, which is generally at the inlet of the highest process gas temperature. In addition, heat recovery steam generators (HRSG) commonly used in combined cycle plants with duct burners are also prone to phosphate hideout and the potential for phosphate wastage, especially when duct burners are in use.

Equilibrium phosphate control<sup>30</sup> makes no attempt to carry boiler water phosphate concentration above its hideout equilibrium level. Equilibrium phosphate levels vary from boiler to boiler, depending on the severity of hideout conditions and must be determined by testing for each unit. EPRI has recently revised and renamed the Equilibrium Treatment philosophy to what is now termed Phosphate Continuum Treatment<sup>4</sup> as illustrated in Figure 5. The maximum Na/PO<sub>4</sub> ratio control boundary is a Na/PO<sub>4</sub> equal to 3.0 plus 1 mg l<sup>-1</sup> (1 ppm) NaOH and the minimum Na/PO<sub>4</sub> control boundary is Na/PO<sub>4</sub> = 3.0. Additionally, there is a minimum pH = 9.0 and a minimum boiler water orthophosphate concentration of 0.2 mg l<sup>-1</sup> (0.2 ppm).

For mixed-bed makeup water systems with no significant sodium leakage and low organic contamination of the makeup and condensate, only trisodium phosphate and caustic soda (when needed) are recommended for Phosphate Continuum Treatment. Monosodium, disodium, and polyphosphates should

not be needed. But for many industrial boiler systems that can have significant sodium leakage from the makeup system or significant organic contaminants in the makeup water or condensate, a wide range of Na:PO<sub>4</sub> molar ratio treatment chemicals might be required to maintain the desired control in a particular boiler system situation.

Phosphate continuum treatment does include the presence of free hydroxide in the boiler water and therefore does present the known concerns associated with caustic in boilers. There is the potential for under deposit caustic gouging in the boiler, the potential for stress corrosion cracking of steam system components in the event of boiler water carry over and the potential for embrittlement damage to the drums if the boiler has mechanical rolled tube joints if one were to leak.

#### 4.28.4.8 All Volatile Treatment

AVT<sup>33,34</sup> helps achieve sufficiently high pH to protect boiler steel without introducing any dissolved solids. It is based on the use of entirely volatile, solid-free chemicals, such as hydrazine or carbohydrazide for oxygen scavenging, plus neutralizing amines or ammonia for boiler water pH control. AVT may be used in drum boilers that have the appropriate feedwater purity and is the only program that can be used in once-through boilers. In drum boilers, AVT may be used for simplicity where phosphate hideout has caused control

Figure 5 Phosphate continuum control chart.

problems on phosphate-pH control programs or where ultra pure steam is required.

A disadvantage of all-volatile treatment for drum boilers is that the boiler water is unbuffered and thus subject to extensive and rapid pH excursions in the event of feedwater contamination. Prompt detection and remedial action is required in the event of any feedwater contamination. A condensate polishing system, either for continuous polishing or for start-up and emergency polishing, is very desirable. Some utilities do operate high pressure drum cycles on AVT without the benefits of polishers, but their systems have extensive instrumentation that allows immediate remedial action to be taken in the event of cycle contamination (including feeding phosphate until the problem is resolved). A mixed-bed polisher is essential in the makeup system.

The AVT program control is simple and highly effective as long as feedwater quality is maintained. Feedwater contamination of an otherwise solid-free system produces undesirable effects immediately. With essentially no buffering capacity in the system, boiler water pH values can reach free acidity levels ( $\text{pH} < 4.3$ ) very rapidly following contamination. This is particularly true in systems using seawater or brackish water for condenser cooling.

Cation conductivity measurements of the boiler water are used to monitor any dissolved solids contamination of the cycle. Cation conductivity is also preferred for condensate and feedwater monitoring since it is very sensitive to changes in dissolved solids concentrations and is not affected by changing the amine or ammonia levels. Specific conductance is used primarily to monitor the level of ammonia or neutralizing amine present in the cycle.

Continuous pH monitoring of the boiler water is desirable, as pH provides another indication of a contamination problem. Boiler water pH values will typically be lower than the feedwater pH because of the volatilization of the amine or ammonia from the boiler water; pH control in the feedwater cycle will vary with cycle metallurgy.

#### **4.28.4.9 Caustic Treatment**

Sodium hydroxide alone can also be used as the solid alkali in internal boiler water treatment for pH control. It is a common practice in high-pressure drum boilers in the United Kingdom, and many of these are high-pressure drum boilers in the electric utility service industry.<sup>4,35</sup> A typical boiler water pH control range

is 9.0–9.4. Caustic can still be very corrosive to carbon steel under concentrated conditions, such as under porous metal oxide deposits on a boiler's heat transfer surfaces, and can cause under deposit corrosion damage. It is therefore very important to keep the boiler's heat transfer surfaces clean by minimizing the feedwater corrosion product transport into the boiler and periodic chemical cleaning. There is also a concern that chloride contamination may increase this corrosion potential, and individual operators have also restricted boiler water chloride limits.

#### **4.28.5 Condensate Treatment**

Condensate is a very valuable commodity (resource) in a boiler system, not only because of its energy content but also because of its high purity. Therefore, the more condensate that can be returned as part of the boiler feedwater, the more efficient the economics are of operating the boiler system.

As condensate is very pure water, very small amounts of contamination can render it extremely corrosive and unsuitable as feedwater. One of the more common contaminants that can depress the pH of the condensate is carbon dioxide. Carbon dioxide can originate from the bicarbonate alkalinity in the makeup water, which decomposes at boiler operating pressure, contributing the carbon dioxide to the steam or from air in leakage into the system. The latter is most likely to occur when the pressure in the condensate system is at or below atmospheric pressure.

In addition, organic materials in the makeup water can decompose in the boiler water, resulting in the formation of low molecular weight organic acids such as acetic, formic, and glycolic acids. These organic acids have volatility characteristics that are a function of pressure. All are considerably stronger acids than carbonic acid and will increase the demand for the neutralizing amine treatment that is commonly employed to neutralize acids and so elevate the condensate pH. Hydrogen sulfide and sulfur dioxide, the products of decomposition of the sodium sulfite oxygen scavenger, that can occur at boiler operating pressures  $> 4.1 \text{ MPa g}$  ( $> 600 \text{ psi g}$ ), can also depress condensate pH and contribute to the amine demand. Depressed pH conditions of the condensate can cause significant corrosion damage to condensate system components.

Dissolved oxygen either not removed by the deaeration processes or that has leaked into the system at points where the pressure is at less than

atmospheric pressure can also cause corrosion damage in the condensate system.

Ammonia can also be considered a contaminant in the condensate if there are copper alloys in the condensate system that can be attacked by the ammonia.

Chemically, four types of treatment are used for condensate system corrosion control: ammonia or neutralizing amines, filming amines, oxygen scavengers/metal passivators, and nonamine filming treatment.

Neutralizing amines and ammonia are volatile, alkaline compounds that are added to either the boiler feedwater or the steam. They function by volatilizing into the steam and redissolving into the condensate. The amines and ammonia chemically neutralize the carbonic acid or any other acid present in the condensate. Then they raise the pH of the condensate to minimize the corrosion of the materials of construction of the condensate system. The most common neutralizing amines in use today are cyclohexylamine, morpholine, diethylaminoethanol, methoxypropylamine, and monoethanolamine. Each has a unique volatility and basicity characteristic.

Industrial boiler systems can have very extensive and complex steam/condensate systems. Complex steam systems that operate at multiple pressure levels, especially where high-pressure condensate is flashed to produce additional low-pressure steam, can concentrate a single treatment amine to one part of the system while simultaneously depleting its concentration in another part of the system due to its unique single, pressure-dependent vapor-to-liquid distribution ratio characteristic. This leads to a situation in which some parts of the complex system can be undertreated, even though from the pH measurement of the combined condensate sample the system appears to be sufficiently treated. The common solution to this situation is the use of an amine treatment product – that may be a combination of multiple amines, each with a different vapor-to-liquid distribution characteristic. In the most complex steam systems, satellite feed to a particular point in the system may still be required to provide adequate corrosion protection. In a simple steam condensate system such as the typical electric utility situation, a single amine or ammonia may provide adequate protection. But there have been many cases where a low volatility amine or the industrial multiple amine philosophies of treatment have provided better protection as measured by a reduction in corrosion product transport, in even the simple system.

Neutralizing amine treatment does not provide protection for the system from dissolved oxygen

attack. The feed of an oxygen scavenger/passivator to the condensate can protect the system against dissolved oxygen attack. Sodium sulfite is typically not used for this application since it contributes non-volatile solids. More typically, one of the volatile organic oxygen scavenger/passivator materials can be used in this application. Preferably though, the source of the oxygen in leakage should be found and corrected.

There can also be situations in which the carbon dioxide content of the steam is so high because of the natural bicarbonate alkalinity of the makeup water, and that treating the condensate with neutralizing amine technology is prohibitively expensive. In this case, a filming amine technology can be used. In the filming amine treatment, the carbon dioxide is not neutralized, but the filming amine forms a nonwetttable barrier on the condensate system components preventing the low pH condensate from coming into contact with the materials. Filming amines also provide protection from dissolved oxygen attack. The amount of filming amine required is related to the surface area of the system. Octadecylamine is a commonly used filming amine. Filming amines have the ability to move corrosion products from the surface of the piping. It is therefore advisable to start with low dosages, which are gradually increased until residual limits are met. There are also proprietary filming amines.

There may be restrictions on amine concentrations in steam when there is contact of that steam with food or food products, when the steam is used for humidification of air or when it can contact certain catalysts used in industrial processes. A nonamine filming corrosion inhibitor technology<sup>36</sup> has been developed for when there is a prohibition on amines in the treated steam.

There are also mechanical means of treating condensate to remove contaminants and preserve its purity for reuse. If corrosion products – typically iron oxides and copper oxides – exist as suspended solids in the condensate, they can be filtered out. Cartridge filters can be used. Condensate polishers, an ion exchange process in which strong acid cation resin is in the sodium or amine form in industrial situations, act primarily as a filter but can also remove hardness that may have come from cooling water contamination of the condensate. In electric utility boiler situations where condensate temperatures are considerably lower, mixed-bed resin polishers (typically a mixture of strong acid cation resin in the hydrogen form and strong base anion resin in the hydroxide form) are used.

These can be deep bed regenerable units or they can be of the powdered resin, one-time-use type. In addition, high gradient electromagnetic filters have been used to remove corrosion products of iron and some copper that are magnetic.

As a final alternative, contaminated condensate can be discarded or diverted rather than returned to the system. The condensate diversion system (condensate dumps) is a system of sensors, valves and piping to detect the contamination of the condensate and divert it to waste. These condensate diversion systems must be properly engineered to detect and divert the contamination in a timely manner to prevent the contamination of the feedwater. This technique is only applicable to systems where the makeup water system capacity can compensate for this lost condensate.

#### **4.28.6 Boiler Treatment During Out-of-Service Conditions**

Boilers constructed out of carbon steel and low chromium alloys up to about 9% chromium content are prone to corrosion at ambient temperatures in contact with untreated, typically aerated, water. The maximum corrosion rate occurs where carbon steel is in contact with a water–air interface. This water–air interface occurs when an operating boiler is taken out of service and the vents are opened to the atmosphere during the cooling process and air displaces the condensing steam. Even if the boiler is drained at this point, depending on the boiler design configuration there may be areas of the boiler that do not drain completely. In addition, in many boiler designs that incorporate superheaters and reheaters, heat transfer surfaces can be of a pendant or other design configuration that is inherently nondrainable. Nondrainable components require special treatment if a wet lay-up method is employed. Water purity must be very high—condensate or demineralized quality—and any treatment chemicals used in the water must be volatile.

Guidelines<sup>37,38</sup> are available for the proper treatment of a boiler in the out-of-service condition. The goal of the guidelines is to use a procedure that generally eliminates the air–water interface. This can be accomplished in a number of ways—by draining the boiler under a positive nitrogen pressure or draining the boiler and installing a desiccant, for example. The appropriate procedure depends on many variables, including the configuration of the boiler and the expected duration of the out-of-service period.

#### **4.28.7 Miscellaneous (But Important) Comments**

Proper sampling is a prerequisite of effectively monitoring a system. Effective monitoring of the makeup water, feedwater, boiler water, steam, and condensate is necessary to control deposition and corrosion within the system. No matter how accurate or precise the analysis of a sample obtained is, if the sample is not truly representative of the stream being sampled, the results are useless.<sup>39</sup> Effective monitoring requires a proper sampling system, adequate sample system purging, the required sample velocity, and appropriate sample handling.<sup>40</sup>

A particular case in point is sampling steam to determine its purity. Isokinetic sampling nozzles and procedures are required.<sup>41</sup> When sampling superheated steam, sample cooling considerations are especially important. The distance between the sampling nozzle and the primary cooler must be minimized—no more than 7 m (20 ft)—and any sample line length between the nozzle and the cooler must be insulated.

The proper sampling and analysis of condensate is especially critical, because of its inherent high purity and the volatility characteristics of both the treatment chemicals and some of the contaminants it might contain.

A stainless steel injection quill must be used to inject treatment chemical into the system. Concentrated treatment chemicals in contact with carbon steel at elevated system operating temperatures present a corrosive situation for the carbon steel. A properly designed and installed chemical injection quill admits the chemical into the fluid stream, so that it is properly diluted in the stream.

### 4.29.1 Introduction

Corrosion inhibitors are used in a wide range of industrial applications. In this chapter, their employment in processing with acids, mining operations, paints and coatings, construction materials, processing electronics packaging, display, and storage is discussed.

### 4.29.2 Processing with Acids

Acids are extensively used in acid pickling, industrial acid cleaning, acid descaling, oil well acidizing, and manufacturing processes in different industries. Inhibitors are used in acid solutions in order to minimize corrosive attack on metals. The selection of suitable inhibitor depends on the type of acid, concentration of the acid, temperature, flow velocity, the presence of dissolved inorganic or organic substances, and the type of metallic material exposed to the acid solution. The most commonly used acids are hydrochloric, sulfuric, nitric, hydrofluoric, citric, formic, and acetic acid.

#### 4.29.2.1 Acid Pickling

Metals or alloys subjected to painting, enameling, galvanizing, electroplating, phosphate coating, cold rolling, and other finishing processes must have a clean surface free from salt or oxide scale. In order to remove the unwanted scale such as mill scale rust, the metal is immersed in an acidic solution known as the acid pickling bath. After the scale is removed by dissolution, the acid may attack the metal. In order to

minimize the attack of the metal, and consumption of the acid, corrosion inhibitors are added to the pickling solution.

Hydrochloric acid is commonly used in the pickling bath. Large-scale continuous treatment such as metal strip and wire pickling and regeneration of depleted pickling solutions are the advantages in using hydrochloric acid instead of sulfuric acid. Other acids, such as nitric, phosphoric, sulfamic, oxalic, tartaric, citric, acetic, and formic acid are used for special applications.

The choice of inhibitor depends on the purpose of acid pickling. If the pickling is for the purpose of removal of mill scale from hot-rolled steel, then the acid concentration, temperature, pickling time, and the type of steel will dictate the selection of the inhibitor. In the case of pickling with HCl, up to 200 g l<sup>-1</sup> are commonly used at 60 °C with a pickling time of about 30 min, depending upon the type of steel and the steel mill operating conditions. Sulfuric acid at 200–300 g l<sup>-1</sup> level and at temperatures up to 90 °C may also be used. These are severe conditions that require effective inhibitors.

The inhibitors used in pickling operations should possess the following requirements:

1. effective inhibition of metal dissolution,
2. lack of overpickling process,
3. effective at low inhibitor concentration,
4. effective at high temperatures,
5. thermal and chemical stability,
6. effective inhibition of hydrogen entry into the metal,
7. good surfactant properties,
8. good foaming properties.

The most important requirement is that the inhibitor minimizes metal dissolution even in the presence of dissolved salts such as ferrous sulfate that promotes metal dissolution. The corrosion rates of steel in 20% sulfuric acid at 90 °C and in 20% sulfuric acid containing 12% ferrous sulfate are 3100 and 5900 g m<sup>-2</sup> h<sup>-1</sup>, respectively. Although there exist inhibitors to counter the accelerating effect of ferrous sulfate, the pickling times are increased. In pickling in sulfuric acid at 60–90 °C to remove the mill scale, inhibitors of high thermal stability should be used. The inhibitors must be stable with respect to hydrolysis, condensation, polymerization, and hydrogenation by nascent hydrogen.

Pickling inhibitors should also minimize the entry of hydrogen into the metal. This aspect is not typically part of the protocol in the evaluation of the inhibitors, since no test involving hydrogen permeation measurement is performed to determine the effect of inhibitor on the kinetics of electrochemical production of hydrogen. Testing an inhibitor only for metal dissolution can be detrimental, as there is no direct relationship between inhibition of metal dissolution and inhibition of hydrogen entry into the metal.

Another important criterion is that the inhibitor should possess high efficiency at low concentrations for economic reasons. A good pickling inhibitor should also possess good surfactant and foaming properties. Usually, the inhibitors have poor surfactant and foaming properties, and therefore, wetting agents, detergents, and foaming agents are added to the commercial inhibitor formulation.

Wetting agents play an important role in facilitating the penetration of pickling acid into the cracks and fissures in the scale and help the removal of the scale. Thus, they are known as 'pickling accelerators.' Some wetting agents have degreasing properties and are known as 'pickling degreasing agents.' Wetting agents by themselves usually have no inhibitive effect. However, the chemical nature of the wetting agents determines whether they improve or decrease the inhibitive effect. Wetting agents and detergents help in producing clean metal surface after the pickling acid drains completely and the rinsing of pickled sample is improved. Wetting agents and detergents also possess foaming activity. When this is insufficient, additional foaming agents may be added to the inhibitor formulation. A stable foam blanket on the surface of the pickling bath reduces the acid spray and conserves heat. It is necessary that wetting agents, detergents, and foaming compounds function effectively over a wide range of temperature, acid concentration, and iron salt concentration. It is obvious that no single inhibitor can meet all

the requirements of an effective inhibitor and hence commercial inhibitors are multicomponent mixtures, which in some cases may contain as many as thirty components. A typical inhibitor formulation consists of a mixture of an active inhibitor, wetting agent, detergent, foaming agent, solvent, and sometimes a cosolvent.

The active inhibitors used in acid pickling are generally mixtures of nitrogen-bearing organic compounds, acetylenic alcohols, and sulfur-containing compounds. The surface-active compounds may be anionics such as alkyl or alkyl phenyl sulfonates or alkyl sulfates with C<sub>10</sub>–C<sub>18</sub> alkyl chains or nonionics such as ethoxylated derivatives of higher alcohols, phenols, or alkylphenols. Nonionics are used when precipitation of iron is to be avoided.

Commercial inhibitor formulations are generally available in solution form. The solvent may be water or the acid in which the inhibitor is to be used. In cases where the inhibitor formulation is not sufficiently soluble, solvents such as methanol, isopropanol, or acetone may be added. Depending upon the amount of solvent or cosolvent, about 5–50 g of the inhibitor is used for 1 l of pickling acid. Corrosion inhibitors used for various metals in HCl containing pickling media are listed in [Table 1](#).

Sulfoxides, sulfides, and thiourea compounds are generally used in a sulfuric acid medium. The common commercial inhibitor formulations consist of dibenzyl sulfoxide, dibenzyl sulfide, thiourea, and di-*O*-tolylthiourea. These inhibitors are effective at high temperatures. Some of the inhibitors used in a sulfuric acid pickling medium are summarized in [Table 2](#).

Iron and steel are passivated in concentrated 65% nitric acid but dissolve in lower concentrations of this acid. Unlike hydrochloric and sulfuric acids, nitric acid is an oxidizing acid, and it is difficult to inhibit high and medium concentrations effectively. Some of the inhibitors used for a nitric acid pickling medium are listed in [Table 3](#). [Tables 4 and 5](#) indicate inhibitors for hydrofluoric acid and phosphoric acid pickling media, respectively. For these two acids, inhibitors are similar to those employed in HCl.

#### 4.29.2.2 Scale Removal by Acids

Scale formation by circulating water or process compounds occurs in power plants, chemical plants, steel mills, paper mills, pipelines, compressor stations, and other industries. Scales or precipitates formed in heat exchangers, boilers, vessels, reactors, piping, and associated equipment reduce heat transfer and cause

**Table 1** Inhibitors employed for various metals in HCl containing pickling media

Medium	Metal or alloy	Inhibitor	References
Hydrochloric acid	Iron, steel	Primary, secondary and tertiary amines, oximes, nitriles, mercaptans, sulfoxides, thioureas, and complexones	
1 M HCl + 2.5% NaCl	Copper, brass	Thiourea, benzimidazole, 2-mercapto-benzothiazole, phenyl thiourea	[1–4]
	Al and its alloys	Aliphatic, aromatic aldehydes, carboxylic acids, ketones, sulfonamides, sulfones, dihedric phenols, tetrazolinium compounds, formazan compounds, sulfoxides, aromatic sulfonic acids, cupferron, <i>N</i> -allyl thiourea, and dibenzyl sulfoxide	[5–7]
HCl + H <sub>3</sub> PO <sub>4</sub> (1 N) 10% HCl		<i>p</i> -Thiocresol and sodium diethyl dithiocarbamate Mixture of aromatic aldehyde, 1 M urea/triethylamine/dodecylamine, > 1 M thiourea and 1-hexyn-3-ol together with alkyl sulfonates	[8]
Hydrochloric acid 5.6 M HCl	Zinc Nickel	Inhibitors used for Al are satisfactory Thiourea and its derivatives <i>O</i> -tolylthiourea and sym-diisopropyl thiourea have 90% inhibition over a wide temperature range	[9]
Hydrochloric acid	Titanium and alloys	Copper sulfate, nitric acid and chromic acid at 0.5–1.0% act as inhibitors. Nitrobenzene, trinitrobenzoic acid, picric acid, benzene arsonic acid at 0.03–0.003 M. Condensation product of formaldehyde with aromatic at 0.003 M	[10–13]

**Table 2** Inhibitors used in a sulfuric acid pickling medium

Metal	Inhibitor and conditions	References
Steel	2-mercaptobenzimidazole	[4]
	2-mercaptobenzimidazole + propargyl alcohol or 1-hexyn-3-ol improved performance	
	Sulfonium compounds at low temperatures	[14–16]
	Thiocyanates, thiourea, thicarbamates, mercaptans produce H <sub>2</sub> S and hydrogen entry into metal. Hazardous mustard gas related compounds from thiourea should be guarded	[17]
	Amines or quaternary ammonium salts + halides Cl <sup>−</sup> /Br <sup>−</sup> /I <sup>−</sup> shows synergetic effect in the order I <sup>−</sup> > Br <sup>−</sup> > Cl <sup>−</sup>	[18]
	Alkylpyridinium salts, <i>p</i> -alkylbenzylpyridinium halides and <i>p</i> -alkylbenzyl quinolinium halides with alkyl = C <sub>8</sub> –C <sub>12</sub> with KI at 10 <sup>−2</sup> to 10 <sup>−3</sup> M at 20–60 °C in 5–30% H <sub>2</sub> SO <sub>4</sub> give good inhibition	
	N-containing inhibitors along with SH <sup>−</sup> from H <sub>2</sub> S show synergistic effect	[19]
	Acetylenic alcohols (0.05–0.01 M). Acetylenic alcohols + halides	
Copper, brass, aluminum	Corrosion rate in boiling H <sub>2</sub> SO <sub>4</sub> : 175 g m <sup>−2</sup> h <sup>−1</sup> . In 0.4% propargyl alcohol or 1-hexyn-3-ol: 1355 g m <sup>−2</sup> h <sup>−1</sup> . Upon introducing KCl 5–1.5 g m <sup>−2</sup> h <sup>−1</sup> (synergism)	[20]
	2-mercaptobenzimidazole + 1 hexyn-3-ol (may be used for boilers)	
Copper	Thiourea	[21–23]
Brass	Quinolines, azoles	[24–26]
Titanium	2,4,6-trinitrophenol, 5-nitroquinoline, 8-nitroquinoline, 0-dinitrobenzene, <i>n</i> -nitroacetanilide, nitrobenzene and picric acid Inhibitors at 0.01–0.001 M in 10% H <sub>2</sub> SO <sub>4</sub> at 60 °C give good inhibition. In 1 M H <sub>2</sub> SO <sub>4</sub> cresolphthalexon, thymolphthalexon, thymol sulfophthalexon at low concentrations and at 80 °C gives good protection	[27–30]

tube failure, plugging, or fouling of equipment. The solid deposits should be removed in addition to preoperational cleaning to remove oxide scales or organic coatings.

The scales may be either organic or inorganic in nature. Inorganic deposits are formed in heat exchangers or steam generators. Typically, these inorganic deposits consist of magnetite, hematite, iron sulfides, calcium, and/or magnesium carbonates, sulfates, phosphates, and silicates. Organic deposits consist of

algae, slime, or moulds. The acids commonly used in scale removal are hydrochloric and hydrofluoric acid, in combination with ammonium bifluoride, sulfuric acid, nitric acid, sulfamic acid, citric acid, acetic acid, hydroxyacetic–formic acid mixture, and phosphoric acid.<sup>61</sup> Some inhibitors used in the removal of scales in hydrochloric acid are given in **Table 6**.

Hydrofluoric acid and ammonium bifluoride are usually added to hydrochloric acid solution to accelerate the removal of iron scales and silicate deposits.

**Table 3** Inhibitors used in nitric acid pickling medium

<i>Metal</i>	<i>Inhibitor and conditions</i>	<i>References</i>
Ferrous metals	Propargyl mercaptan, propargyl sulfide, ethane dithiol, thioacetic acid, mercaptoacetic acid, diethyl sulfide, benzyl-2-methyl pyridine thiocyanate and thiourea. Steel vessels	Transport of 50–116% H <sub>3</sub> PO <sub>4</sub> – dodecylamine or 2-amino bicyclohexyl (0.03–0.10%) in KI (0.007–0.014%)	[57]
Aluminum alloys	Urotropin, <i>p</i> -toluidine in H <sub>3</sub> PO <sub>4</sub> medium are effective inhibitors	[58, 59]
Titanium	Conc. H <sub>3</sub> PO <sub>4</sub> – inhibited by (NH <sub>4</sub> ) <sub>2</sub> MoO <sub>4</sub> + K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub>	[60]

**Table 6** Inhibitors used in scale removal in a hydrochloric acid medium

<i>Metals/scales</i>	<i>Inhibitor and conditions</i>	<i>References</i>
Scale of calcium and iron salts	5–15 wt% HCl at 80 °C. Mixture of imines, thiourea and alkynols	[62]
Zinc	Mixtures of <i>N,N'</i> -dicyclohexylthiourea, ethynycyclohexanol, and polyaminomethylene phosphate	
Carbon steel	Sulfonium compounds	[15, 16]
Scale in refineries	14% HCl containing 33–37 g l <sup>-1</sup> of hexamethylene tetramine	[63]
Copper with a scale of magnetite in high pressure boilers	Mixture of thiourea or its derivatives and hexahydropyrimidine-2-thione	

Magnetite and hematite scales may be removed by hydrofluoric acid. Mannich bases, thiourea and its derivatives, and alkynols may be used as inhibitors in hydrofluoric acid medium.<sup>54</sup> The condensation product of diethyl and dibutyl thiourea with hexamethylene tetramine can also act as an inhibitor in HF medium for scale removal.<sup>64</sup>

Sulfuric acid at 5–15 wt% may be used to remove oxide scales. This acid cannot be used to remove

calcium deposits because the product, calcium sulfate, is insoluble. Concentrated sulfuric acid in combination with nitric acid is used to remove organics, coke. Mixtures of quaternary ammonium compounds, alkynols, and sulfur compounds may be used for inhibition in a dilute sulfuric acid solution. Nitric acid is useful in cleaning stainless steel or plastic equipment. Inhibitors are not stable in the strong oxidizing nitric acid and are not used in the case of carbon steel or copper alloys.

Sulfamic acid is useful in the removal of calcium scales but not iron oxides. A mixture of sulfamic acid and sodium chloride can remove iron oxide scale through slow generation of hydrochloric acid. Sulfamic acid can be used in cleaning equipment containing copper, brass, stainless steel, and galvanized steel. Inhibitors at 10 wt% used in sulfuric acid medium may be used in sulfamic acid solution. Sulfamic acid is extensively used in cleaning evaporations in sugar mills made of cast iron with copper heat exchangers.

Citric acid is used in cleaning heat exchangers of nuclear plants, which are susceptible to chloride attack. Iron oxide scales can be removed by repeated treatment with citric acid. Inhibitors for sulfuric acid solutions can be used in citric acid medium.

Acetic acid may be used where chloride-free removal of carbonate scales in equipment made of aluminum is necessary. Inhibitors used in sulfuric acid find application in acetic acid medium. A mixture of 2 wt% of hydroxyacetic acid and 1 wt% of formic acid may be used to remove magnetite from high-pressure steam generators and superheater sections of boilers. Again, inhibitors functioning in a sulfuric acid medium may be employed here.

#### 4.29.2.3 Acidizing Oil Wells

Acids are generally used in oil and gas wells to stimulate the oil or gas flow from the well and to remove any encrustations in the well. Acids such as hydrochloric acid are forced, under high pressure, through the hole into the rock formation to produce fractures around the hole. The fractures are then filled with sand in order to prevent the fractures from closing and allow the gas or oil to permeate. About 10–15 wt% of HCl is generally used. A mixture of hydrochloric and hydrofluoric acids is used when the formation is rich in silicate. It is necessary to protect the equipment from corrosion due to the acid by use of inhibitors. The inhibitors used should be stable up to 150 °C and in some cases, 260 °C. Some inhibitors used in acidizing oil and gas wells are given in Table 7.

#### 4.29.3 Mining Industry

In the mining industry, the three corrosive environments are (i) mine air, (ii) mine dust, and (iii) mine water. Mine air causes atmospheric corrosion of mining equipment to an extent determined by the composition of mine air, humidity, and temperature.

**Table 7** Inhibitors used during acidizing oil and gas wells

<i>Inhibitor and conditions</i>	<i>References</i>
Mixtures of nitrogen containing compounds, acetylenic compounds and surfactants	[65]
C <sub>12</sub> –C <sub>18</sub> primary amines, cyclohexyl amine, aniline, methyl anilines, alkyl pyridines, benzimidazole, and rosin amine condensed with formaldehyde	
Amines together with cuprous iodide	[66]
Propargyl alcohol or 1-hexyn-3-ol gives improved inhibition at high temperatures	[67]
Alkynoxymethyl amines.	
Acetylenic inhibitors together with ferrous ions gives rise to protective surface films due to iron catalyzed condensation and polymerization	[58, 68]

Mine air is deficient in oxygen and contains significant amounts of oxides of sulfur and nitrogen. Sulfur dioxide results from burning coal, and oxides of nitrogen originate from the use of underground explosives. The oxides of sulfur and nitrogen combined with high humidity and temperature cause corrosion of mining equipment.

Coal mine dust contains pyrite in coal seams and gypsum, which is used for dusting in order to reduce the amount of combustible particles. The sulfur content of coal is corrosive to mining equipment. Sulfur dioxide, produced by the oxidation of pyrite, reacts with hygroscopic constituents and generates sulfuric acid, which attacks the metal.

Mine waters are unique in that they vary in composition from mine to mine. The pH values range from 2.8 to 12.3. Chloride values range from 5 to 10 500 ppm and sulfate ranges from 57 to 5100 ppm. Low pH, high chloride and sulfate content of mine water are conducive to severe corrosion.

Microbial corrosion can also be a problem. *Thiobacillus* species, such as thiooxydants, are common soil or water organisms. These entities oxidize sulfur, generating corrosive sulfuric acid. Sulfate-reducing bacteria generate hydrogen sulfide, which is also corrosive.

Mitigation of corrosion in the mining industry is done by the addition of (i) passivating inhibitors, (ii) precipitation inhibitors, and (iii) adsorption inhibitors. Chromates and phosphates are typical of passivating inhibitors and function by blocking the anodic reaction. These inhibitors are incorporated into the oxide film on the metal, thereby stabilizing the oxide film and preventing further dissolution. The concentration of the chromate inhibitor used is

**Table 8** Inhibitors and their performance in acidic mine waters

<i>Inhibitor</i>	<i>Type</i>	<i>Performance</i>
Sodium silicate	Precipitation	Fair to good
Potassium oxalate	Precipitation	Fair to good
Sodium nitrite	Passivation	Good
Sodium molybdate	Passivation	Fair to good
Phosphonate–phosphate	Precipitation	Excellent
Phosphonate–silicate	Precipitation	Fair to good

critical because low concentrations give rise to underprotection resulting in pitting corrosion.

Precipitation inhibitors consisting, for example, of zinc salts block the cathodic reaction by precipitation at the cathode due to elevated local pH values. Pitting is not a problem, even though complete coverage is not attained, because the anodic sites are unaffected by the inhibitors and the number of unprotected cathodic sites are insufficient to promote anodic dissolution.

In general, organic inhibitors can be considered as adsorption inhibitors. The functional group in the inhibitor molecule such as amino, carboxyl, or hydroxyl readily absorbs on the metal surface forming a type of bond and blocks the anodic and/or cathodic sites.

The performance of some inhibitors tested in acid mine water are given in [Table 8](#).<sup>69</sup> It should be noted that corrosion inhibition by potassium oxalate involves the formation of tris-oxalate iron complex, which is photosensitive. The complex decomposes in the presence of light to  $\beta$ -ferrous oxalate.

The product of photochemical decomposition,  $\beta$ -ferrous oxalate, is deposited on the metal and protects the metal from corrosion. This is the first example of photochemical corrosion inhibition.<sup>70</sup>

Corrosion inhibitors have been used in corrosive wear loss of grinding balls in grinding Cu–Zn–Fe sulfide ore. Many inorganic inhibitors both as single component and binary mixtures were used and a binary mixture of sodium chromate and sodium carbonate reduced the corrosive wear of the grinding balls by 30%.<sup>71</sup>

#### 4.29.4 Paints and Coatings

The primary function of an organic coating on a metallic structure is to provide a protective barrier between the metal and the external corrosive

**Table 9** Inhibitors employed in coating formulations for steel core

<i>Compounds</i>
<i>Calcium</i>
Carbonate
Molybdate
Plumbate
<i>Chromium</i>

Chalk
China clay
Iron oxide
Strontium chromate
Talcum
Titanium dioxide

environment. Paints are used for both corrosion protection and cosmetic purpose. Usually corrosion inhibitors are incorporated in the primer. The inhibitors used in coatings can be anodic, cathodic, or mixed. Some examples of the inhibitors incorporated into coating formulations suitable for steel core are given in [Table 9](#).<sup>69</sup>

Some of the components are used as fillers. Zinc and calcium molybdate are effective at low levels ( $\sim 3\%$ ), and are nontoxic. These compounds may be used in place of chromates, which are toxic. Red lead protects the steel by combining with the corrosion products of iron. Red lead, zinc oxide, and calcium carbonate form soaps with linseed oil and then decompose in the presence of oxygen and water into a lead salt of azelaic acid, which promotes cathodic reduction of oxygen. This helps to stabilize the iron oxide film by maintaining a suitable potential. Calcium plumbate increases the pH and thus inhibits corrosion. The lead suboxide in oleoresinous coatings forms lead soaps on the metal surface and blocks the anodic

sites by adsorption. Lead suboxide in linseed oil primer is found to penetrate the rust film and into crevices of rusted steel.

Inhibition by chromate-based pigments is similar to that of dissolved chromate, and this is supported by the slight solubility of the pigment.<sup>72</sup> Chromate ions are adsorbed onto the surface followed by the formation of a passive film containing  $\text{Cr}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ . Both potassium chromate and zinc chromate protect the steel. Potassium chromate protects by interfering with the anodic reaction, while zinc chromate also forms a zinc hydroxide film inhibiting the cathodic reaction.

Zinc, along with cadmium and strontium, chromate has been used in the protection of aluminum involving crevices. These compounds are reduced at cathodic sites and hydrogen evolution is prevented. Disbonding of coatings is due to hydrogen evolution and addition of cadmium phosphate shows improved inhibition.

Chromates, such as zinc chromate, potassium or barium chromate, may be used as primers in various vehicles including linseed oil, long oil linseed pentaalkyd, double-boiled linseed oil for corrosion inhibition. Good protection was obtained with modified phenolic stand oil and epoxy ester primers, as confirmed by neutral pH, noble potentials, and formation of soap, which covers the zinc chromate causing water repulsion.

Some pigments based on lead, silicate, and phosphate, along with some applications, are given in [Table 10](#).

The coatings discussed so far involve heavy metal compounds that are toxic with the exception of molybdates and phosphates. Thus, development of environmentally friendly coatings containing tannins

has received attention. It is necessary that the fabrication of raw products, surface pretreatment and application of coating, use of coated structure, and recycling and elimination steps should be considered from the point of environmental impact. Tannins are used as corrosion inhibitors in water-based paints. Such paints can be applied directly on rusted objects without pretreatment, such as sandblasting.

The mechanism of protection by tannins in paints has been investigated by many studies.<sup>77–83</sup> An early proposal was the formation of an insoluble chelate complex at anodic sites.<sup>78</sup> The insoluble chelate complex may act as an insulator between anodic and cathodic sites because of the cross-linked structure of the complex.<sup>79</sup>

Tannins are also known to convert ‘active’ rust into nonreactive oxide such as magnetite.<sup>80</sup> The insoluble complex formed may act as a barrier for the diffusion of oxygen.<sup>77</sup> The action of tannins appears to depend upon the properties of paint-rust system and upon the amount of rust present.<sup>81</sup> X-ray photoelectron data and Mössbauer spectra showed an increase in the ratio of ferrous to ferric ions when the rust was treated with tannins.<sup>82</sup> Vacchini<sup>83</sup> showed the dissolution of rust by tannins and the formation of a complex that acted as a barrier for the diffusion of oxygen.

#### 4.29.5 Construction Materials

Corrosion inhibition in reinforced concrete structures involves a single addition of the inhibitor. On this basis, the criteria for effective corrosion inhibition in concrete are that (i) the inhibitor should be soluble in mixing water to allow homogeneous distribution and not readily leachable from concrete;

**Table 10** Some pigments in common use

<i>Pigment</i>	<i>Comments</i>	<i>References</i>
Red lead	Red lead in linseed oil used as primer for steel structures. Red lead oxide forms soluble soaps with vehicle	[73]
Lead silicochromate	Consists of silicate case coated with its own pigment. Anticorrosive due to lead and passivation due to chromate. Coating with this is comparable to red lead in linseed oil in protection. Protection of passenger car bottoms by using priming coats with the pigment achieved	[74]
Barium oxide-iron oxide	Developed for corrosion control of fertilizer plants. Corrosion protection is satisfactory	[75]
Zinc phosphate/barium phosphate primer	Nontoxic and promotes excellent intercoat adhesion. The primer converts the metal to metal phosphate. This primer reduces diffusion of ions through paint film. Zinc phosphates-iron oxide in linseed stand oil performed better than red oxide-zinc chromate in field tests	[76]

- (ii) the inhibitor must be compatible with the aqueous cement phase, to render its full protection potential;
- (iii) the concentration of the inhibitor should not adversely affect the properties of the concrete; and
- (iv) the consumption rate of the inhibitor should be low.

The most extensively used inhibitor in concrete is calcium nitrite, although organic inhibitors have become prominent in recent years. Calcium nitrite has been used as an inhibitor for concrete on a large scale. Calcium nitrite provides corrosion protection in the presence of chlorides, does not affect the properties of concrete, and is readily available for commercial use in concrete.

Calcium nitrite, an anodic inhibitor, is thought to be responsible for the constant repair of weak spots in the protective iron oxide film as well as the following reactions:

The nitrite ion is believed to compete with chloride and hydroxyl ions in the reaction with ferrous ions. As the nitrite ion helps to repair the flaws in the oxide film the probability of chloride attack at the flaws of the oxide film and dissolution of the oxide film as soluble chloro complexes of iron are minimized. Given that nitrite inhibitor is involved in repairing the oxide film and the oxide films are of the order of monolayers, nitrite is not consumed to a great extent.

Pozzolans (complex silicate of iron, aluminum, and calcium) are used to prevent corrosion by reducing permeability of concrete to chloride. Microsilica is one of the most effective pozzolans because its small particle size acts as a filler and increases its chemical reactivity. Calcium nitrite is compatible with microsilica and should provide corrosion protection in the presence of chloride. Calcium nitrite is also found to improve the performance of fly ash concrete and concretes containing slag. Calcium nitrite is also effective in the protection of cracked concrete.

Organic inhibitors have been used as an alternative to the commonly used calcium nitrite. The organic inhibitors, referred to as organic corrosion inhibiting admixtures (OCIA), adsorb on the metal surface through a polar functional group, while non-polar hydrophobic groups repel the aqueous corrosive fluids and interact with each other to form a tight film of aggregates on the metal surface. The tight hydrophobic film is also impermeable to chloride ingress into the concrete.

The performance of organic amines and esters with both uncracked and precracked concrete

samples has been compared with precracked samples treated with calcium nitrite.<sup>84</sup> The organic inhibitors lowered the corrosion rates to a significant extent. The onset of corrosion in samples treated with organic inhibitors occurred after 180 days, and the corresponding times were 30 and 5 days in the case of calcium nitrite treated samples and uninhibited samples, respectively. The ingress of chloride was highest in calcium nitrite treated samples and least in organic inhibitor treated samples. The higher chloride ingress in samples treated with nitrite is attributed to the accelerating effect of nitrite resulting in a more permeable concrete matrix. The blocking of pores by organic inhibitor results in low ingress of chloride in samples treated with organic inhibitor.

A mixture of glycerophosphate and nitrite showed synergistic behavior in the protection of steel in mortars.<sup>85</sup> Other inhibitors used in reinforced steel are ethanolamine,<sup>86</sup> poly alcohols, polyphenols, and sugars. Alkanolamine has been shown to be an effective inhibitor and to migrate through the pores when it is injected into the cavities.<sup>87</sup>

#### 4.29.6 Processing Electronics Packaging, Paper Display, and Storage

Some organic compounds with vapor pressures in the range  $10^{-2}$  to  $10^{-7}$  mmHg volatilize and condense on the surface of a structure to be protected from corrosion in a closed space. These types of compounds are known as vapor-phase corrosion inhibitors; a list of common vapor-phase inhibitors, along with their vapor pressures, is given in Table 11. Vapor-phase corrosion inhibitors are particularly useful in impeding atmospheric corrosion. Atmospheric corrosion is expensive and results from individual or combined action of moisture, oxygen, and pollutants such as  $\text{SO}_2$  and  $\text{NO}_2$ .

Most effective vapor-phase inhibitors consist of a weak volatile base and a weak volatile acid. Amine nitrites undergo hydrolysis and provide inhibition

The pH of the medium is critical to the effective inhibition by vapor-phase inhibitors.

The application of vapor-phase inhibitors varies, depending upon the composition of the object to be protected, as well as the conditions of storage of the object. Storage conditions dictate the aggressiveness

**Table 11** Common vapor phase inhibitors and their saturated vapor pressures

Substance	Temperature (°C)	Vapor pressure (mmHg)	Melting point (°C)
Morpholine	20	8.0	
Benzylamine	29	1.0	
Cyclohexylamine carbonate	25.3	0.397	
Diisopropylamine nitrite	21	$4.84 \times 10^{-3}$	139
Morpholine nitrite	21	$3 \times 10^{-3}$	
Dicyclohexylamine nitrite	21	$1.3 \times 10^{-4}$	179
Cyclohexylamine benzoate	21	$8.0 \times 10^{-5}$	
Dicyclohexylamine caprylate	21	$5.5 \times 10^{-4}$	
Guainidine chromate	21	$1.0 \times 10^{-5}$	
Hexamethyleneimine benzoate	41	$8.0 \times 10^{-4}$	64
Hexamethyleneamine nitrobenzoate	41	$1.0 \times 10^{-6}$	132
Dicyclohexylamine benzoate	41	$1.2 \times 10^{-6}$	210

of the treatment. The storage conditions requiring progressively more aggressive treatments are (i) enclosed nonventilated area; (ii) uncovered inside storage; (iii) covered outside storage; and (iv) uncovered outside storage.

Vapor-phase inhibitors are either oil or water soluble and applied in the form of powders, sprays, or impregnated papers and foams. A controlled-release inhibitor formulation can be employed, which is designed to release the inhibitor at a controlled rate over a specified period. Polymer encapsulation may be used for controlled release, where a rate-controlling membrane encloses a cavity that contains the inhibitor either dispersed or in solution. The membrane can be porous or nonporous and the inhibitor is in a reservoir in a fluid state that maintains a constant amount in the reservoir until an excess amount is released. This results in a steady-state release of the inhibitor that follows Fick's law.

In addition to encapsulation, the inhibitor can be dispersed in a polymer matrix, from which the inhibitor is extracted. There are two types of matrix device. In the first type, the release of the active inhibitor is controlled by diffusion through the matrix upon erosion of the matrix. In the second type, the release of the inhibitor is initiated by the penetration of some species, such as water, from the environment into the matrix. On reaction with water, the active inhibitor is released because of hydrolysis.

Some common examples of this type are esters, anhydrides, and acetals.

### 4.27.1 Introduction

Water has a relatively high heat capacity. In fact, water has the second highest heat capacity of any known substance, after ammonia, and is slow to absorb and reject heat. These properties are because of hydrogen bonding at the molecular level and make water valuable in cooling and heating processes and systems such as heating, ventilation, and air conditioning (HVAC) systems. Water is commonly employed as a heat transfer fluid, that is, a vehicle for transporting heat to some distant point of use, or away from a process, or for the uptake/removal of heat via a heat exchanger, cooling tower, or similar device.

The water may be employed in liquid, gaseous (steam), or solid (ice) form, depending upon the specific process. For example:

- liquid water is employed for HVAC condenser cooling;
- steam is the medium for many boiler plants;
- ice can be used in HVAC thermal energy storage systems.

However, all water sources ultimately employed for industrial process or in HVAC system applications, and even potable grade water contain a variety of contaminants, and as a result of a combination of the contaminants (including dissolved oxygen), the specific process operating conditions, and the materials of equipment construction, the water can act as a scale-forming or corrosive fluid.

Various forms of modification and active control of the process environment are usually necessary to maintain operational efficiency and reduce the potential for corrosion, fouling, or premature system failure. This is usually achieved through the selective use of filters, softening equipment, certain nonchemical devices, pH management, and/or the addition of specialty chemical inhibitors, together with appropriate technical overseeing.

Other heat transfer fluids, such as ethylene or propylene glycol, may be used under certain circumstances, for example where the fluid in a pipe is exposed to freezing winter temperatures. After prolonged usage, glycols may become corrosive because of thermal breakdown or microbial action, and modification of the fluid by, for example, raising the pH and adding a chemical inhibitor, may be necessary.

Water is also vital to the existence of all life forms, where it acts as a vehicle for the transport of essential minerals and vitamins to all parts of the organism.

In developed societies potable water is delivered under pressure through pipes, and these pipes (especially metal pipes) together with pumps, valves, etc. may also be subject to scaling, fouling, or corrosive action. Thus, modification and active control of potable water systems to prevent corrosion and other problems may also be necessary. Here, we may choose to use less corrodible materials of construction, employ potable grade phosphate or silicate chemicals (for corrosion control or threshold stabilization of scale-forming alkaline earth salts), or use approved disinfection processes, such as chlorination, bromination, ozonation, or the application of chlorine dioxide from an on-site generator.

The active modification of an aqueous heating, cooling, or process environment (and usually that of other heat transfer fluids) to prevent or minimize corrosion, scaling, or biological or inorganic fouling, together with the provision of appropriate monitoring and control is termed 'water treatment.'

### 4.27.2 Heat Capacity and Latent Heat

It has already been stated that a major benefit of using water in cooling, heating, and potable water systems is because of its high heat capacity. As more heat energy is required to increase the temperature of a substance with high specific heat capacity than to increase the temperature of one with a low specific heat capacity, from an engineering design position it is convenient for water to be employed as a vehicle for the transport of heat.

The measure of the heat energy required to increase the temperature of a unit quantity of a substance by a certain temperature interval is known as the specific heat capacity (the symbol is  $c$ ), also known simply as specific heat. When measuring specific heat capacity in science and engineering, the unit quantity of a substance is often in terms of mass: either the gram or kilogram. For example, the heat energy required to raise water's temperature by 1 K (equal to 1 °C) is  $4184 \text{ J kg}^{-1}$  – the kilogram being the specified quantity. This is at a sea-level pressure of one standard atmosphere (101.325 kPa) – approximately a bar (which is 100 000 Pa) and a temperature of 15 °C. Scientifically, this measure would be expressed as  $c = 4184 \text{ J kg}^{-1} \text{ K}^{-1}$ .

- The specific heat capacity of liquid water is  $4.184 \text{ kJ kg}^{-1} \text{ K}^{-1}$ .

- The specific heat capacity of water vapor is  $1.996 \text{ kJ kg}^{-1} \text{ K}^{-1}$ .
- The specific heat capacity of ice is  $2.108 \text{ kJ kg}^{-1} \text{ K}^{-1}$ .

In the United States, which tends not to commonly use SI units, the specific heat of water is defined as the amount of heat necessary to increase the temperature of one pound of water by  $1^\circ\text{F}$ , and is given as 1 British Thermal Unit (Btu).

When thermal energy is withdrawn from a liquid such as water, or a solid such as ice, the temperature falls, as in a chiller plant, a cooling tower, or an evaporative condenser. When you add heat energy the temperature rises, as in a boiler. If sufficient energy is withdrawn or added, a change of state can occur, as in a steam-raising boiler (steam generator). To go from liquid to solid, the molecules of a substance must become more ordered. To maintain the order of a solid, extra heat must be withdrawn. In the other direction, to create disorder on going from solid crystal ice to liquid water, extra heat must be added.

The enthalpy of vaporization (the symbol is  $\Delta H_v$ ), also known as the heat of vaporization or latent heat of evaporation, is the energy required to transform a given quantity of a substance into a gas. It is often measured at the normal boiling point of a substance, although tabulated values are usually corrected to 298 K.

The enthalpy of fusion (the symbol is  $\Delta H_{\text{fus}}$ ), also known variously as the latent heat of fusion, the enthalpy change of fusion, or the specific melting heat, is the amount of thermal energy which must be absorbed or evolved for 1 mol of a substance to change state from a solid to a liquid or vice versa. The temperature at which it occurs is called the melting point and at this point, extra energy is required (the heat of fusion).

- The heat of vaporization of water is  $2260 \text{ kJ kg}^{-1}$ .
- The heat of fusion of water is  $333.55 \text{ kJ kg}^{-1}$ .

In the United States, the latent heat of fusion is usually defined in non-SI units, and is given as the amount of heat required to change one pound of a given substance from solid to liquid state without change in temperature. It requires 144 Btu to change one pound of ice at  $32^\circ\text{F}$  to one pound of water at  $32^\circ\text{F}$ , the heat of fusion of ice being 144 Btu per pound.

Also, the latent heat of vaporization in non-SI units is defined as the amount of heat required to change one pound of a given substance from liquid to vapor state without change in temperature. It requires a considerable amount of additional heat

energy (970 Btu) to change one pound of water from  $212^\circ\text{F}$  to 1 pound of steam at  $212^\circ\text{F}$ . This high energy input requirement is again because of hydrogen bonding, and results in steam occupying 20 600 times the volume of liquid water at  $100^\circ\text{C}$  ( $212^\circ\text{F}$ ). The steam, usually under high pressure, is available both as a medium for transporting heat energy and for mechanical work (as in steam engines, steam pumps, and for turning turbine blades in the generation of electrical energy).

In North American refrigeration and air conditioning applications, 1 'ton of cooling' is a common unit, and is  $12\,000 \text{ Btu h}^{-1}$ . It is the amount of power needed to melt one ton of ice in 24 h, and is approximately 3.51 kW. Cooling towers, boiler plants, and chiller plants are commonly rated in tons.

#### **4.27.3 The Use of Water in Industrial Cooling and Heating Systems and Potable Applications**

Global withdrawal rates of freshwater continue to grow at more than double the rate of population growth.<sup>1</sup> Withdrawal rates of estuarine and salt water also continue to grow at a similar rate. Unfortunately, freshwater availability and distribution is not divided up fairly or evenly around the globe and this has created difficulties in developing countries.

Where water is conserved by being reused in industrial processes, such as employing treated waste water as a makeup stream for a cooling tower, there is a significant benefit in terms of a reduced need for potable grade water, but the contaminants create increased risks of corrosion and scale. Thus, to ensure clean waterside conditions and optimum operational efficiencies, active modification of the process environment is necessary to control the risks, yet still obtain the benefits of water recycling.

Slightly less than  $5000 \text{ km}^3$  of freshwater is available globally for production of potable quality water and for general commercial and industrial applications<sup>2</sup> ( $1 \text{ km}^3 = 264.2 \times 10^9 \text{ US gallon}$ ). Half the world exists on only  $95 \text{ l day}^{-1}$  (25 US gallon per day) but in developed countries water consumption is much higher, for example consumption in the USA per capita is around  $5.1 \text{ m}^3 \text{ day}^{-1}$  (1350 US gallon per day), of which personal use accounts for  $0.53 \text{ m}^3 \text{ day}^{-1}$  (140 US gallon per day).<sup>3,4</sup> Much of the water consumed is used for agricultural purposes (typically 50–60% or more), especially irrigation, with water for industrial and potable use being significantly lower.

A closer look at, for example, the United States' estimated 408 billion gallons per day ( $1.54 \times 10^9 \text{ m}^3 \text{ day}^{-1}$ ) use of freshwater shows the following breakup<sup>3,4</sup>:

- Agriculture accounts for some 49% of this consumption (200 billion gallons per day), with 160 billion gallons per day being used for irrigation purposes (although water for irrigation in California may be as high as 80%).
- Public supply, delivering water to homes, businesses, and industry is some 11% (45 billion gallons per day).
- Self-supplied industrial users, together with mining, livestock producers, aquaculture, and domestic wells account for 7% (29 billion gallons per day).
- Thermoelectric power generation is the primary user of the balance of surface freshwater consumed, at around 134 billion gallons per day or 33% of the total.<sup>5</sup>

US thermoelectric power generators also use more than 61 billion gallons per day of saline water for once-through cooling. So, total water withdrawal rates for the US thermoelectric power industry are 195–200 billion gallons per day.<sup>5</sup> Most of this is used for cooling water duty, although some water is required for boiler feed, ash handling, and other functions. (Heavy industrial processors also withdraw significant quantities of saline water for once-through use – again primarily for cooling water duty.)

Wet cooling requirements are about  $25 \text{ gal kWh}^{-1}$  of electricity generated, although once-through cooling systems typically require  $37.7 \text{ gal kWh}^{-1}$ , whereas recirculating cooling water processes only require  $1.2 \text{ gal kWh}^{-1}$ .<sup>6</sup> This dramatic saving in water is the primary reason for the extensive and global use of cooling towers for all types of application. Again, however, the savings in water consumption also create a risk, as the contaminants present in the cooling water concentrate as 'pure' water evaporates from the tower and fresh makeup brings additional contaminants with it, which can reach saturation levels and result in scale, fouling and corrosion problems, if left uncontrolled.

Apart from the power industry, it can be seen that the various businesses and industry in the United States collectively use about 45 billion gallons of water per day ( $170.3 \times 10^6 \text{ m}^3 \text{ day}^{-1}$ ). Globally, water consumption for similar activities is perhaps 200 billion gallons per day ( $757 \times 10^6 \text{ m}^3 \text{ day}^{-1}$ ).

Often more than 50% of this total water consumption is for heating and cooling purposes, so there

exists, not only a great opportunity for further reduction, recycling and reuse of water, but the potential for a wide range of scaling, fouling, and corrosion problems to develop! The risk of waterside problems are a constant threat to process operating efficiency and costs, and to the quality of potable water supplies, necessitating a proactive approach to modification and control of water system environments, that is, an active water treatment program.

Eight examples of heating, cooling, and potable equipment using water are shown in [Photos 1\(a\)–1\(h\)](#).

#### 4.27.4 The Need for Water Treatment to Control Waterside Heating, Cooling and Potable Water Environments

Water treatment encompasses a wide range of technologies and activities designed to prevent serious corrosion, failures, and malfunction of equipment using or delivering water, and to ensure the health and safety of operators and other personnel who may come into contact with or use the water.

Water is a universal solvent. Whenever it comes into contact with a foreign substance, there is some dissolution of that substance. Some substances dissolve at faster rates than others, but in all cases a definite interaction occurs between water and whatever it contacts. It is because of this interaction that problems occur in equipment such as boilers or cooling-water systems in which water is used as a heat-transfer medium. In systems open to the atmosphere, corrosion problems are made worse by additional impurities picked up by the water from the atmosphere and can have a devastating effect on equipment such as heat exchangers, cooling towers, valves, pumps, etc.

Corrosion alone is a major cause of failure and costly replacement of equipment and so is itself a good reason why water treatment is necessary. As a result, environmental maintenance, surveillance, and the application of water treating equipment, chemistries and controls are required of almost all water systems, including cooling towers and evaporative condensers, especially in view of the awareness of the risks of infection that may result from systems that are poorly designed, dirty, and/or badly maintained.

The risks of waterborne infection from bacterial organisms such as *Legionella* species are not limited to cooling systems, but can emanate from almost any type of building facility water systems, especially

domestic hot and cold water services. Also, pools, spa baths, showers, and humidifier pans are sources of microbial contamination, as are HVAC systems that are poorly maintained or not cleaned on a regular basis. Microbial growth in HVAC water tanks and pans is distinct from, but may also be linked to

problems developing in air handling systems – which typically involve mold organisms such as *Aspergillus* sp. or *Stachybotrys* sp. (the same organisms that can proliferate behind damp sheetrock walls and insulation).

For water treatment to be effective it is necessary to understand the problems water and its

**Photo 1** Continued

**Photo 1** (a) D-type, 2 drum watertube boiler, (b) firetube boiler, (c) cooling towers, (d) chiller plant, (e) surface condenser, (f) retort cooker; (g) domestic water storage tanks, (h) hotel hot water storage vessels.

contaminants can cause, the mechanisms by which water causes these problems, and the effects that result. A review of the results of analysis of the contaminants in any particular water, plus a thorough understanding of the chain of cause and effect leads to a diagnosis of the potential or actual problems, and from there a solution may be found. The solution may be based on a 'standard' item of equipment, chemistry, or operational protocol or local environmental control, but is usually tailored in some way to meet the specialized and often unique operating conditions that may be found.

Corrosion is a pervasive problem and the direct losses because of corrosion of metals for replacement and protection globally are staggering, and as most costs studies available only look at the direct costs, the true costs are even higher. Indirect costs of corrosion include the costs of labor for repairs and corrosion management, temporary equipment, loss of revenue, and reliability. Annual direct costs because of corrosion in the United States have been reliably estimated at \$276 billion in a study published by NACE International.<sup>6</sup> Examples of these costs include the following:

- drinking water and sewer water systems: \$36 billion per year;
- production and manufacturing industry: \$17.6 billion per year; and
- electrical utilities: \$6.9 billion per year.

Another report, measuring the impact of corrosion in the US Department of Defense (DOD),<sup>7</sup> found that the annual cost of corrosion ranged from \$10 billion to \$20 billion in direct maintenance costs,

with the annual cost of corrosion to Navy ships being \$2.43 billion.

Protection against corrosion may include organic coatings, cathodic and anodic protection, use of more resistant alloys, and water treatment products (such as corrosion inhibitors) and services. Water treatment is usually focused on modifying the waterside environment by rendering the water less scale-forming or corrosive, and by use of inhibitors which act at the metal–water interface to form a passive chemical barrier composed of an oxide, carbonate, silicate, molybdate, hydroxide, phosphate, phosphonate, etc.

The formation of scale and deposits, sludges, and biological foulants are other problems that can increase operating costs, and reduce efficiency and the economical service life of equipment such as HVAC systems. There is no reason to believe that the maintenance and additional energy costs associated with scaling and fouling problems are not at least as high as those associated with corrosion. **Photos 2(a) and 2(b)** show the results of corrosion and deposition in pipes.

Scale formation is insidious and will interfere with the normal efficient transfer of heat energy from one side to the other of a heat exchanger. The degree of interference with this transfer of heat is called the fouling factor. Manufacturers' recommended design fouling-factor for air-conditioning chillers and condensers is usually 0.000 5. In HVAC systems, high fouling factors cause an increase in condensing temperature of the refrigerant gas which, in turn, increases energy requirements to compress the refrigerant at that higher temperature. It can be seen from **Figure 1** that there is a significant increase in condensing temperature with increase in fouling factor.

**Photo 2** (a) Pipe metal wastage because of corrosion and (b) pipe deposits due primarily to scaling, but also corrosion.

Where scales or deposits occur in boilers, they are often also associated with under deposit and pitting-types of corrosion, and can consist of various substances including iron, silica, calcium, magnesium, carbonates, sulfate, and phosphates. Each of these, when deposited on a boiler tube, contributes in some degree to the insulation of the tube, which reduces the rate of heat transfer from the hot gases or fire through the boiler metal to the boiling water. This leads to an increase in the temperature of the boiler tube and can result in metal bulges, blisters, and eventually, boiler failure and possibly an explosion.

#### 4.27.5 The Hydrologic Cycle and Water Chemistry

As discussed earlier, water and its contaminants are responsible for the corrosion of metals and formation of deposits on heat-transfer surfaces, which in turn

**Figure 1** Effect of scale on condensing temperature.

reduce efficiency, waste energy, and increase costs. The effects of corrosion and deposits have been illustrated in the earlier pictures and in order to see how these problems can be prevented, it is first necessary to understand their basic causes, why and how they occur. This understanding starts with a review of the hydrologic cycle (see [Figure 2](#)).

The hydrologic cycle consists of three stages: evaporation, condensation, and precipitation, and begins when the rays of the sun heat surface waters on the earth, which vaporize and rise into the troposphere, a thin layer of air and moisture approximately 11 km (7 miles) thick surrounding the earth. Clouds of condensed moisture form in the troposphere and contact cold air currents when carried over land by the wind, causing precipitation, such as rain or snow. In this manner, water returns to the earth's surface, only to repeat the cycle. Throughout the hydrologic cycle, the water absorbs impurities.

The concentration of inorganic and organic contaminants, and greenhouse gases in the atmosphere varies depending on geographic location, the sources of pollution (such as basic industrial facilities, fossil-fueled utility power generators, and high density cities and their automobiles), and the weather patterns, including prevailing winds and air currents. Rainwater, containing these contaminants and dissolved gases, is often at a pH of below 7.0 (i.e., slightly acidic) and in contact with the earth surface, it will tend to dissolve and absorb many of the minerals of the earth via reactions including hydrolysis and hydration. The reaction rate with the earth's minerals

**Figure 2** Hydrologic cycle.

(such as gypsum, calcite, dolomite, and quartz) is increased with more acidic rainfall, and calcium, silica, magnesium, iron, minerals, etc. are dissolved. As a general rule (although there are numerous exceptions):

- Surface water in lakes, rivers, streams, ponds, and reservoirs usually contain fewer minerals but more dissolved gases.
- Underground water supplies are a result of surface waters' percolation through the soil and rock, and usually contain higher concentrations of minerals and less dissolved gases.

While falling through the atmosphere, water dissolves gases such as oxygen, nitrogen, carbon dioxide, nitrogen oxides, sulfur oxides, and other trace elements and polluting chemicals. The quantity of dissolved gases in water is governed by Henry's Law of partial pressures, and the solubility of these gases in water decreases with increasing temperature. Gases found in water include the following:

- *Carbon dioxide.* In the earth's atmosphere carbon dioxide is considered a trace gas, and currently occurs at an average concentration of about  $385 \text{ mg l}^{-1}$  (parts per million) by volume or  $582 \text{ mg l}^{-1}$  by mass.<sup>8</sup> It is present in both surface and underground water supplies as a dissolved gas. Surface waters normally contain less than 10 ppm free carbon dioxide, while some ground waters

may easily exceed that concentration. Carbon dioxide is readily soluble in water forming the weak acid, carbonic acid, as follows:

Over the ordinary temperature range ( $0\text{--}30^\circ\text{C}$ ) its solubility is about 200 times that of oxygen. Calcium and magnesium combine with carbon dioxide to form carbonates and bicarbonates. Larger amounts of carbon dioxide are absorbed from the decay of organic matter in the water and its environs. Carbon dioxide contributes significantly to corrosion by making water acidic. This increases its capability to dissolve metals in boiler plant (especially steam condensate systems, and cooling systems). The breakdown of calcium bicarbonate with the release of carbon dioxide under conditions of stress and increase of the concentration of contaminants, because of evaporation processes, are the primary reasons for the increase in cooling water pH during operation.

- *Oxygen.* Oxygen gas (dioxygen  $\text{O}_2$ ) is the second most common component of the Earth's atmosphere taking up 21.0% of its volume and 23.1% of its mass and is essential for life. The allotrope

ozone (trioxygen  $O_3$ ) is produced in the upper atmosphere. It is very reactive and near the earth's surface it is a pollutant formed as a by-product of automobile exhaust.<sup>9</sup> However, oxygen is the basic factor in the corrosion process and is, in fact, one of the essential elements in the corrosion process of metals. Therefore, dissolved oxygen in water is important to us in the study of corrosion and deposits. In cold water it is present at  $8\text{--}9\text{ mg l}^{-1}$ .

- **Sulfur oxides.** Sulfur oxide gases are present in the atmosphere as pollutants from the combustion of fuels containing sulfur, such as coal and fuel oil. In large urban areas, the quantity of sulfur oxides that are absorbed by surface water supplies and aerated waters used in cooling towers can be significant. Also when dissolved in water, sulfur oxides form acids which create a corrosive atmosphere.

- **Hydrogen sulfide.** The odor typical of rotten eggs, which is found in some water, is because of the presence of hydrogen sulfide. This gas comes from decaying organic matter and from sulfur deposits, and is a constituent of sewer gas, marsh gas, and coal gas. Hydrogen sulfide reacts with water to form hydrosulfuric acid, a slightly acidic solution. It can be present in water but because of its acidic reaction, it is very corrosive and must be removed or neutralized. Hydrogen sulfide forms when acidic water reacts with sulfide minerals such as pyrite (iron sulfide).

- **Nitrogen oxides.** Nitrogen oxides are also present in the atmosphere, both naturally and from pollutants created by the combustion process. These also form acids when absorbed by water, and contribute to the corrosion process.

When rainwater, containing carbonic acid (resulting from the reaction between dissolved carbon dioxide gas and water), reaches chalk or limestone strata, it will dissolve some of the mineral forming the soluble salt

calcium bicarbonate, as shown in the reaction below. The presence of this salt is of particular importance where water is employed for any type of heat transfer duty, as under heat load conditions it can quickly breakdown and produce scale on the heat-transfer surfaces. Scale inhibits the efficient transfer of heat and also provides an environment for problems of underdeposit corrosion to develop. Thus, modification of the local waterside environment ('water treatment') is required to prevent this common but costly problem.

Apart from the dissolved gases discussed above, contaminants in water will typically include various common dissolved minerals and/or salts. Some of the common minerals that may be dissolved in water include the following:

- silicates, for example, quartz, augite, mica, chert, feldspar, hornblende;
- carbonates, for example, calcite, dolomite, limestone;
- halides, for example, halite, fluorite;
- oxides, for example, hematite, ice, magnetite, bauxite;
- sulfates, for example, anhydrite, gypsum;
- sulfides, for example, galena, pyrite;
- natural elements, for example, copper, sulfur, gold, silver; and
- phosphates, for example, apatite.

Any or all the above may enter into solution as the mineral or a related salt, and are considered contaminants, although some of them may be desirable in potable water (to provide taste and minerals necessary for good health). Some common dissolved minerals and salts found in water include the following:

- calcium bicarbonate:  $Ca(HCO_3)_2$ ;
- calcium chloride:  $CaCl_2$ ;
- calcium sulfate:  $CaSO_4$ ;
- calcium carbonate:  $CaCO_3$ ;
- magnesium bicarbonate:  $Mg(HCO_3)_2$ ;
- magnesium chloride:  $MgCl_2$ ;
- magnesium sulfate:  $MgSO_4$ ;
- sodium bicarbonate:  $NaHCO_3$ ;

- sodium chloride:  $\text{NaCl}$ ;
- sodium phosphate:  $\text{Na}_3\text{PO}_4$ ;
- sodium sulfate:  $\text{Na}_2\text{SO}_4$ ;
- ferrous bicarbonate:  $\text{Fe}(\text{HCO}_3)_2$ ;
- manganous bicarbonate:  $\text{Mn}(\text{HCO}_3)_2$ ;
- silica:  $\text{SiO}_2$ ;
- silicic acid:  $\text{H}_2\text{SiO}_3$ ; and
- sodium silicate:  $\text{Na}_2\text{SiO}_3$ .

The concentration of these species are usually in the milligrams per liter (parts per million) range, and are regularly tested in all waters used in industrial cooling and heating systems. Also, pH and the various forms of alkalinity are tested. For potable use and more critical industrial and process applications, the water will be tested for trace organics present and other low-level contaminants – which may only be present in the microgram per liter (part per billion) range – as well as some of the dissolved gases. **Table 1** is an example of a typical, but basic, water analysis report.

Common tests include the following:

- **Alkalinity.** Alkalinity is the quantity of dissolved alkaline earth minerals expressed as calcium carbonate. It is the measured carbonate and bicarbonate minerals calculated as calcium carbonate, as that is the primary alkaline earth mineral contributing to alkalinity. Alkalinity is also measured and calculated as the hydroxide when that is present. All natural waters contain some quantity of alkalinity. It contributes to scale formation because its presence encourages deposition of calcium carbonate or lime scale. However, the alkalinity content is important in modifying the corrosive behavior of water in both boiler plant and cooling system environments. Thus, titration of the various types of process waters found in heating and cooling systems for alkalinity concentration is regularly carried out by plant operators and water treatment company service providers. Calculation of the various forms of alkalinity can be obtained from using **Table 2**.
- **Phenolphthalein alkalinity** (P alkalinity) is that portion of the alkalinity titrated with acid to pH 8.2 end-point.
- **Total alkalinity** (or M alkalinity) is that portion of the alkalinity titrated with methyl orange to pH 4.2.
- **pH.** In practical terms, pH is the measure of the relative strength of acidity or alkalinity of water, and is a value calculated from the hydrogen-ion concentration in water. The pH scale is based on the negative decimal logarithm of the hydrogen ion activity in an aqueous solution and ranges from 0 to 14. Hence, because of the logarithmic nature

**Table 1** Water analysis report sheet

<b>Water Analysis:</b>		
<i>Location</i>	<i>Industrial water</i>	<i>City water</i>
<i>Date of sampling</i>		
<i>Date of testing</i>		
<b>Parameter</b>		
pH	9.2	7.5
P alkalinity, as $\text{CaCO}_3$ ( $\text{mg l}^{-1}$ )	10	0
Bicarbonates, as $\text{CaCO}_3$ ( $\text{mg l}^{-1}$ )	52	167
Carbonates, as $\text{CaCO}_3$ ( $\text{mg l}^{-1}$ )	20	–
Hydroxides, as $\text{CaCO}_3$ ( $\text{mg l}^{-1}$ )	–	–
M (total) alkalinity, as $\text{CaCO}_3$ ( $\text{mg l}^{-1}$ )	72	167
Total hardness, as $\text{CaCO}_3$ ( $\text{mg l}^{-1}$ )	159	149
Sulfate, as $\text{SO}_4$ ( $\text{mg l}^{-1}$ )	181	
Silica, as $\text{SiO}_2$ ( $\text{mg l}^{-1}$ )	7.7	10
Iron, as Fe ( $\text{mg l}^{-1}$ )	0.3	0.1
Chloride, as NaCl ( $\text{mg l}^{-1}$ )	23	187
Specific conductance ( $\mu\text{S cm}^{-1}$ )	415	815
Total dissolved solids ( $\text{mg l}^{-1}$ )	270	501
Molybdate, as $\text{Na}_2\text{MoO}_4$ ( $\text{mg l}^{-1}$ )	–	–
Phosphate, as $\text{PO}_4$ ( $\text{mg l}^{-1}$ )	1.0	0.1
Sulfite, as $\text{Na}_2\text{SO}_3$	–	–

of the scale, water with a pH value of 4.0 is 100 times more acid in strength than water with a pH value of 6.0. Water is corrosive, if the pH value is on the acidic side. It will tend to be scale-forming, if the pH value is alkaline. A pH of 7.0 is neutral and indicates a balance between acidity and alkalinity.

pH is an important metric and increasing the concentration of dissolved minerals in a boiler water or cooling water, by permitting the release of steam or evaporation, results in a higher pH and less tendency for general corrosion processes to occur, but increases the risks of deposition of supersaturated salts.

By virtue of its logarithmic nature, pH is a dimensionless quantity. pH is defined in terms of the activity of hydrogen ions ( $\text{H}^+$ ) in solution<sup>10</sup>:

$$\text{pH} = -\lg[a(\text{H}^+)] = -\lg[m(\text{H}^+)\gamma_m(\text{H}^+)/m^\ominus]$$

**Table 2** Interpretation of 'P' and 'M' Alkalinity Titrations

Ions	$P = 0$	$P < M/2$	$P = M/2$	$P > M/2$	$P = M$
(OH)	0	0	0	$2P - M$	M
$\text{CO}_3$	0	$2P$	M	$2(M - P)$	0
$\text{HCO}_3$	M	$M - 2P$	0	0	0

Bicarbonates and hydroxides do not exist together.  $\text{CO}_2$  does not exist with carbonates. 'P' Alkalinity =  $\frac{1}{2}$  carbonates and all hydroxides. 'M' Alkalinity = all hydroxides, carbonates and bicarbonates.

where  $a(\text{H}^+)$  is the activity of hydrogen ion ( $\text{H}^+$ ) in aqueous solution;  $\text{H}^+(\text{aq})$ ,  $\gamma_m(\text{H}^+)$  are the activity coefficient of  $\text{H}^+(\text{aq})$  (molality basis) at molality  $m(\text{H}^+)$ ;  $m^\ominus = 1 \text{ mol kg}^{-1}$ , and is the standard molality. Notes:

1. Molality is the number of moles of solute dissolved in 1 kg of solvent.
2. pH cannot be measured independently because calculation of the activity involves the activity coefficient of a single ion. Thus it can be regarded only as a notional definition.
3. The establishment of primary pH standards requires the application of the concept of 'primary method of measurement,' and involves the use of a cell without transference, known as the Harned cell.
  - **Hardness.** Hardness is the total calcium, magnesium, iron, and trace amounts of other metallic elements in water, which contributes to the 'hard' feel of water. Hardness is also calculated as calcium carbonate, because it is the primary component contributing to hardness. Hardness causes lime deposits or scale in equipment.
  - **Temporary hardness or carbonate hardness** can be removed by heating water to precipitate as carbonate salt (e.g., bicarbonates), equal to or less than the P alkalinity.
  - **Permanent hardness or noncarbonate hardness** is that portion of total hardness that cannot be removed by heating water (e.g., sulfate hardness), and is the difference between total hardness and total alkalinity.
  - **Iron, manganese, and alumina.** These dissolved or suspended metallic elements are present in water supplies in varying quantities. They are objectionable because they contribute to a flat metallic taste and form deposits. These soluble metals can react with oxygen in water exposed to the atmosphere, and form oxides which precipitate and

cause cloudiness, or 'red water.' This red color, particularly from iron, causes staining of plumbing fixtures, sinks, and porcelain china and is a cause of common laundry discoloration.

- **Silica.** Silica is dissolved when water flows through sand or silica-bearing rock (such as quartz). Silica is the cause of very hard and tenacious scales that can form and cause severe heat-transfer problems. It is present, either dissolved in water as silicate or suspended in a very fine, invisible form, as colloidal silica.
- **Chlorides.** Chlorides are the sum total of the dissolved chloride salts of sodium, potassium, calcium, and magnesium present in water. Sodium chloride, which is common salt, and calcium chloride are the most common of the chloride minerals found in water. Chloride is a depassivating ion. It reduces the corrosion resistance of many metals, especially those that naturally and strongly passivate to form a protective oxide layer, such as stainless steels and aluminum, by attacking the passivated film.<sup>11</sup>

High chloride waters will increase the risk of stress corrosion cracking in austenitic stainless steels (e.g., 304/304L, 316/316L) and will tend to increase both the general rate of corrosion and attack in localized areas, often causing pitting type corrosion. Corrosion from chlorides always tends to be more severe when the metal surface is shielded by foulants or semiporous deposits, such as silt and muds, as various forms of selective corrosion can take place with often very high concentrations of chloride forming under the deposit. The most logical environmental modification response, therefore, to using a makeup water source with high chlorides is to be scrupulous in maintaining clean metal surfaces in the cooling system. This can take the form of more frequent physical cleaning and the use of side-stream filters, polymer dispersants, and biodispersants. Raising the level of chemical inhibitor treatment is a further and usually beneficial response, although this may require a reevaluation of the cooling system economics.

- **Sulfates.** Sulfates are the dissolved sulfate salts of sodium, potassium, calcium, and magnesium in the water. They are present because of dissolution of sulfate-bearing rock such as gypsum. Calcium and magnesium sulfate scale is very hard and difficult to remove and greatly interferes with heat transfer.

Sulfates are causative agents (along with oxygen, hydrogen, etc.) of the various types of concentration cell corrosion that results in pits, crevice attack, or tuberculation. They have reactions similar to chloride. In addition, and again similarly to chlorides, the presence of sulfate ions contributes strongly to increases in electrical conductivity and hence influences potential increases in corrosion rates. Sulfates are also involved in depassivation, especially where deposits or foulants are involved and can be reduced by selective microbial action (sulfate reducing organisms), that are almost always present in biofilms, producing deep pits of corroded steel.<sup>11</sup>

- *Total dissolved solids.* The total dissolved solids (TDSs) reported in water analyses are the sum of dissolved minerals including the carbonates, chlorides, sulfates, and all others that are present. The dissolved solids contribute to both scale formation and corrosion in heat-transfer equipment.
- *Suspended matter.* Suspended matter is finely divided organic and inorganic substances found in water. It is caused by clay silt and microscopic organisms, which are dispersed throughout the water, giving it a cloudy appearance. The measure of suspended matter is turbidity. Turbidity is determined by the intensity of light scattered by the suspended matter in the water.

#### 4.27.6 Waterside Problems Resulting from Mineral Scales, Muds, and Sludges

Calcium carbonate scale is the most common and costly water-caused scaling problem encountered in industrial boilers, cooling systems, condensers, and HVAC equipments. Other scale components include calcium sulfate, phosphate, magnesium carbonate, iron, silica, and manganese. In most cases, scales contain a complex mixture of mineral salts because scale forms gradually and deposits the different minerals in a variety of forms.

Depending upon the specific boiler plant/cooling system/HVAC/potable waterside environment, mineral scales can develop on heat transfer surfaces in crystalline form (which is usually hard and tenacious) or in noncrystalline or amorphous form, which often is sludge-like and removable by high-pressure water jetting or similar cleaning process. Often, problems of scaling and deposits are accompanied by problems

of corrosion as well. Corrosion can take place under scales and may be due, in part, to similar causes, such as a failure to pre-clean a water system, inadequate chemical treatment, or ongoing maintenance.

Many salts such as sodium chloride (table salt) are more soluble in hot water than in cold; however, calcium and magnesium salts have an inverse solubility and dissolve more readily and in greater quantity in cold water than in hot water. This property, as discussed earlier, is primarily responsible for the problem of mineral scale formation on heat-transfer surfaces in HVAC equipments. The high energy and maintenance costs that can result stems from the significant interference with heat transfer caused by water mineral scale deposits, corrosion, and the problems associated with the removal of scale deposits (usually requiring some form of acid cleaning).

As shown earlier, typically, calcium carbonate enters solution through the following reactions:

However, with the application of heat, the reaction reverses and because of the low solubility of calcium carbonate, carbonate scale develops as follows:

A list of some commonly found mineral components of deposits and foulants is given in [Table 3](#).

##### 4.27.6.1 Problems from Mineral Scales, Muds, and Sludges in Boilers

Scale in boilers is a direct result of precipitation of the calcium, magnesium, iron, and silica minerals present in the boiler feedwater and can be prevented by removing a portion or all of the scale-forming ingredients in the boiler water makeup supply with external water-softening equipment such as ion-exchange or lime/lime-soda softening. An example of scaled boiler tubes is shown in [Photo 3](#).

Modification of the waterside environment will also require additional ‘polishing’ chemical treatments (internal boiler water treatment), usually on the basis

**Table 3** Commonly found mineral components of deposits and foulants

<i>Salt/oxide</i>	<i>Mineral</i>	<i>Formula</i>
Calcium carbonate	Aragonite	$\text{CaCO}_3$
	Calcite	$\text{CaCO}_3$
Calcium phosphate	Hydroxyapatite	$\text{Ca}_{10}(\text{OH})_2(\text{PO}_4)_6$
	Tricalcium phosphate	$\text{Ca}_3(\text{PO}_4)_2$
Calcium sulfate	Anhydrite	$\text{CaSO}_4$
	Gypsum	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$
	Hemihydrate	$\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$
Copper oxide	Cuprite	$\text{Cu}_2\text{O}$
Iron carbonate	Siderite	$\text{FeCO}_3$
Iron oxide	Haematite	$\text{Fe}_2\text{O}_3$
	$\alpha$ -Iron oxide (paramagnetic)	$\alpha\text{-Fe}_2\text{O}_3$
	$\gamma$ -Iron oxide (ferromagnetic)	$\gamma\text{-Fe}_2\text{O}_3$
	Lepidocrocite	$\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$
	Magnetite	$\text{Fe}_3\text{O}_4 \cdot \text{H}_2\text{O}$
Iron sulfide	Troilite	$\text{FeS}$
Magnesium hydroxide	Brucite	$\text{Mg}(\text{OH})_2$
Magnesium phosphate	Magnesium hydroxyphosphate	$3\text{Mg}_3(\text{PO}_4)_2 \cdot \text{Mg}(\text{OH})_2$
Magnesium silicate	Serpentine	$3\text{MgO} \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$
